Unconjugated (Indirect) Bilirubin

The breakdown of heme leads to the production of unconjugated bilirubin, which is water insoluble, is tightly bound to albumin, and does not pass into the urine. Excessive production of unconjugated bilirubin typically follows an episode of hemolysis. In the absence of concomitant liver disease or biliary obstruction, the liver can usually handle the extra bilirubin, and only a modest rise in serum levels is observed. There is a substantial increase in bile pigment excretion, leading to large quantities of stercobilinogen in the stool. A patient with hemolysis may therefore be slightly jaundiced with normal-colored urine and stools. Blood tests reveal that 60 to 85% of bilirubin is indirect.¹²⁷

Possible causes of indirect hyperbilirubinemia include a variety of disorders that result in significant hemolysis or ineffective erythropoiesis. The diagnosis of indirect hyperbilirubinemia attributable to hemolysis is confirmed by an elevated serum lactate dehydrogenase (LDH) level, a decreased serum haptoglobin level, and evidence of hemolysis on microscopic examination of the blood smear.

Disorders associated with defects in hepatic bilirubin uptake or conjugation can also produce unconjugated hyperbilirubinemia. The most common of these, Gilbert syndrome, is a benign condition affecting up to 7% of the general population.^{128,129} It is not a single disease but a heterogeneous group of disorders, all of which are characterized by a homozygosity for a defect in the promoter controlling the transcription of the UDP glucuronyl transferase I gene.¹³⁰ The consequent impairment of bilirubin glucuronidation presents as a mild unconjugated hyperbilirubinemia. The elevated bilirubin level is usually detected on routine blood testing, and affected patients may report that their skin turns yellow when they are fatigued or at stressful times (e.g., after missing meals, after vomiting, or in the presence of an infection). Other causes of an unconjugated hyperbilirubinemia are beyond the scope of this chapter.

Approach to the Jaundiced Patient

MRCP = magnetic resonance cholangiopancreatography; ERCP = endoscopic retrograde cholangiopancreatography; PTC = percutaneous transhepatic cholangiography; EUS = endoscopic ultrasonography; CT = computed tomography; MRI = magnetic resonance imaging; MRA = magnetic resonance angiography.

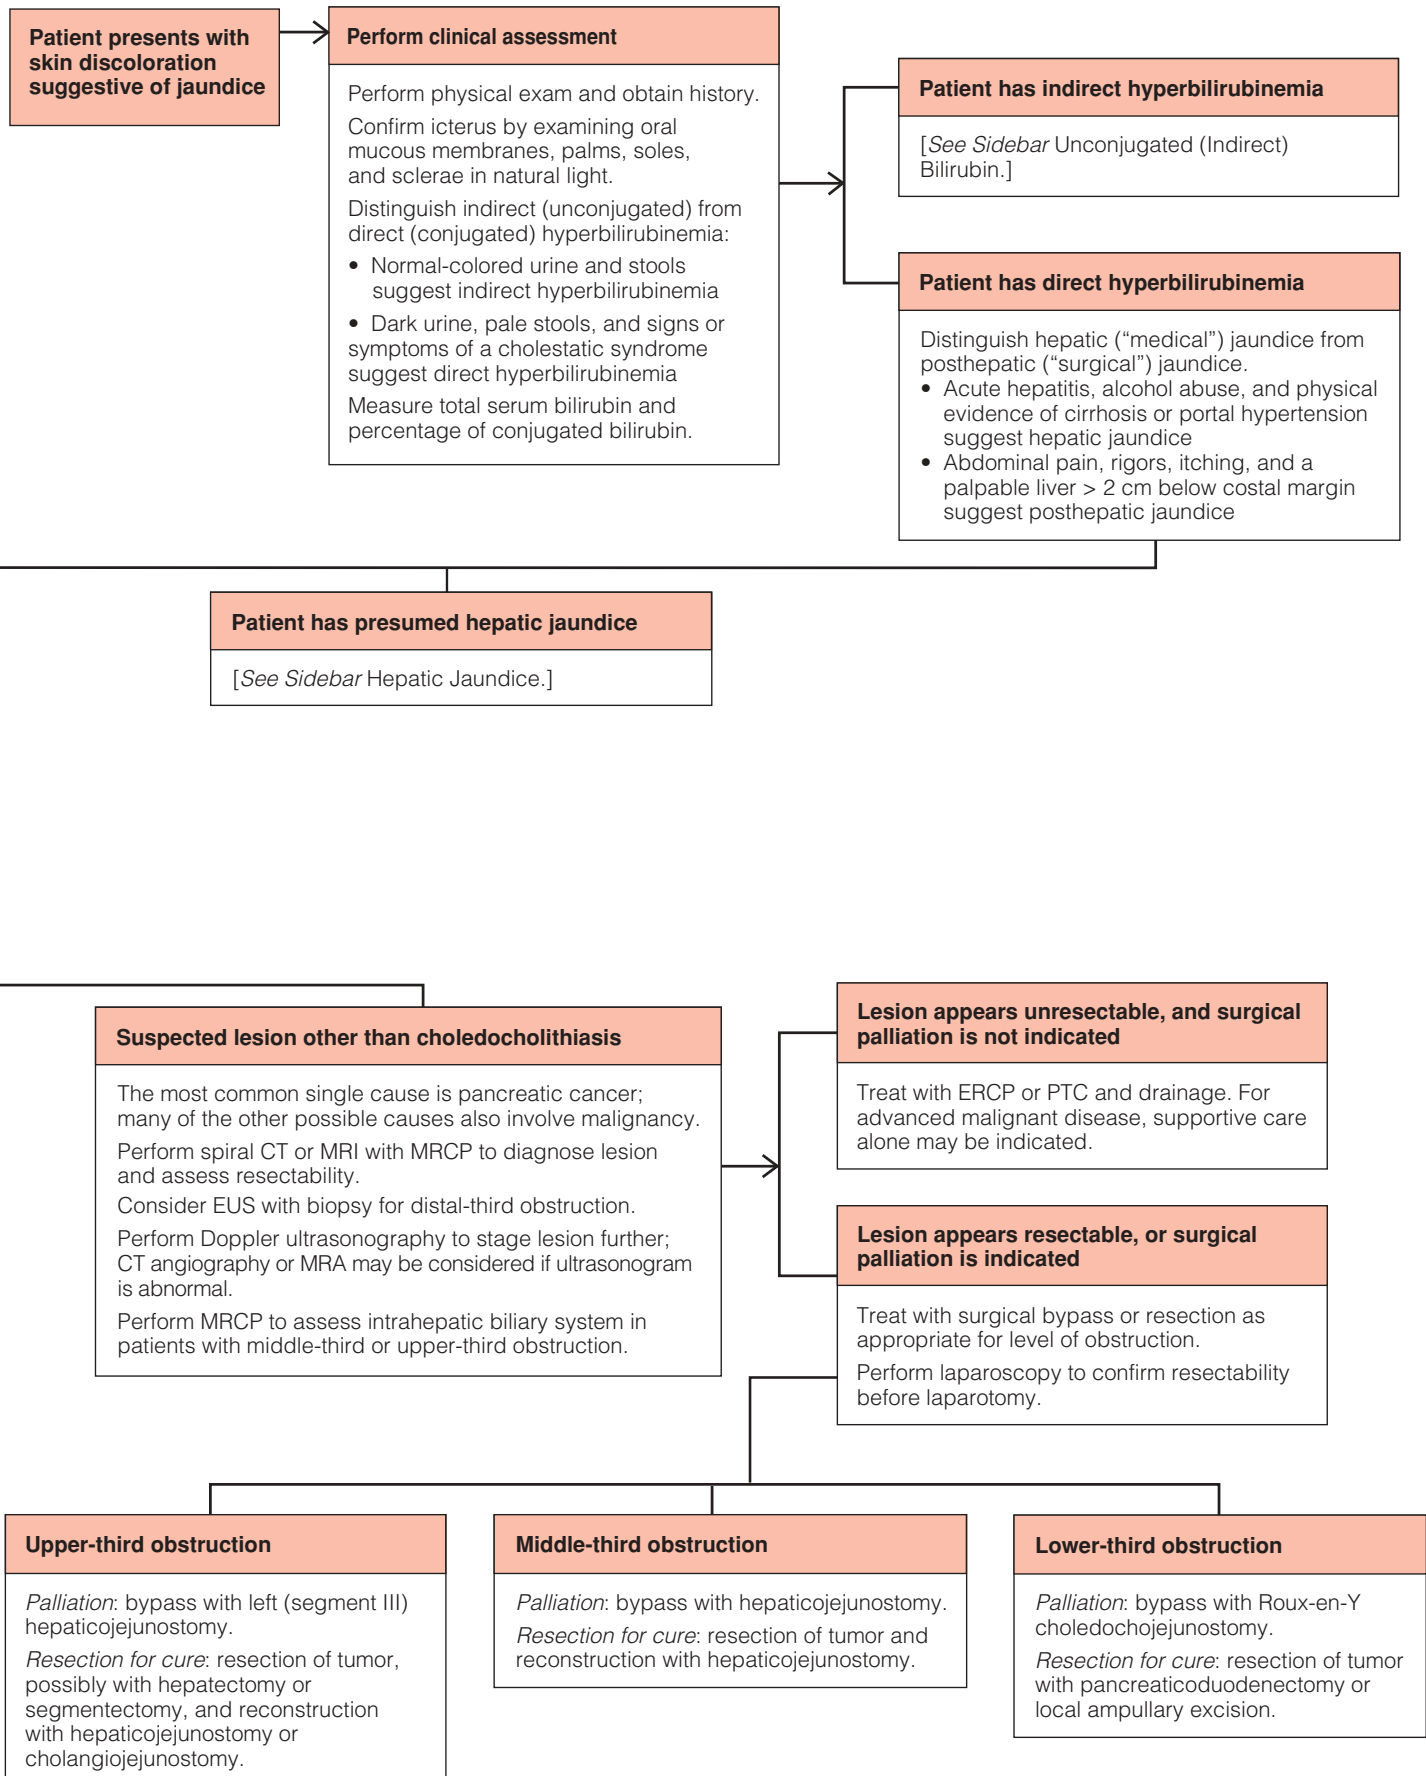

Table 1 Causes of Unconjugated Hyperbilirubinemia

RBC = red blood cell.

symptoms of a cholestatic syndrome (see below), the serum bilirubin fractionation usually indicates that conjugated bilirubin is predominant. Rarely, the clinical picture may be secondary to a massive increase in both direct and indirect bilirubin production after the latter has overcome the ability of the hepatocytes to secrete conjugated bilirubin.

It is nearly always possible to distinguish between direct and indirect hyperbilirubinemia on clinical grounds alone.³ Our emphasis here is on direct hyperbilirubinemia, which is the type that is more relevant to general surgeons.

Cholestatic Syndrome

The term “cholestasis” refers to decreased delivery of bilirubin into the intestine (and subsequent accumulation in the hepatocytes and in blood), irrespective of the underlying cause. When cholestasis is mild, it may not be associated with clinical jaundice. As it worsens, a conjugated hyperbilirubinemia develops that presents as jaundice. The conjugated hyperbilirubinemia may derive either from a defect in hepatocellular function (hepatic jaundice, also referred to as nonobstructive or medical jaundice) or from a blockage somewhere in the biliary tree (posthepatic jaundice, also referred to as obstructive or surgical jaundice). In this chapter, we refer to hepatic and posthepatic causes of jaundice, reserving the term cholestasis for the specific clinical syndrome that is attributable to a chronic lack of delivery of bile into the intestine. This syndrome is characterized by signs and symptoms that are related either to the conjugated hyperbilirubinemia or to chronic malabsorption of fat-soluble vitamins (i.e., vitamins A, D, E, and K): jaundice, dark urine, pale stools, pruritus, bruising, steatorrhea, night blindness, osteomalacia, and neuromuscular weakness.⁴

HEPATIC VERSUS POSTHEPATIC JAUNDICE

Once the presence of direct hyperbilirubinemia is confirmed, the next step is to determine whether the jaundice is hepatic or posthepatic. A number of authors have studied the reliability of clinical assessment for making this determination.^{5–16} The sensitivities of history, physical examination, and blood tests alone range from 70 to 95%,^{5–10} whereas the specificities are approximately 75%.^{9,10} The overall accuracy of clinical assessment of hepatic and posthepatic causes of jaundice ranges from 87 to 97%.^{7,11} Clinically,

hepatic jaundice is most often signaled by acute hepatitis, a history of alcohol abuse, or physical findings reflecting cirrhosis or portal hypertension¹²; posthepatic jaundice is most often signaled by abdominal pain, rigors, itching, or a palpable liver more than 2 cm below the costal margin.¹³

By using discriminant analysis in a pediatric patient population, two investigators were able to isolate three biochemical tests that differentiated between biliary atresia and intrahepatic cholestasis with an accuracy of 95%: total serum bilirubin concentration, alkaline phosphatase level, and γ -glutamyltranspeptidase level.¹⁴ Serum transaminase levels added no independent information of significance to the model. Another multivariate analysis model demonstrated that patients with posthepatic jaundice were younger, had a longer history of jaundice, were more likely to present with fever, and had greater elevations of serum protein concentrations and shorter coagulation times than patients with hepatic jaundice.¹⁵ This model, however, despite its 96% sensitivity (greater than that of any single radiologic diagnostic modality), could not accurately predict the level of a biliary obstruction. Other investigators have reported similar findings,^{7,11,12} and most agree that strategies that omit ultrasonography are clearly inferior.¹⁶

In summary, a clinical approach supported by simple biochemical evaluation displays good predictive ability to distinguish hepatic from posthepatic jaundice; however, a clinical approach alone does not accurately identify the level of biliary obstruction in a patient with posthepatic jaundice.

The remainder of this chapter focuses primarily on management of posthepatic jaundice; hepatic jaundice is less often seen and dealt with by general surgeons [see Table 2 and Sidebar Hepatic Jaundice].

IMAGING

Once the history has been obtained and bedside and laboratory assessments have been completed, the next step is imaging, the goals of which

are (1) to confirm the presence of an extrahepatic obstruction (i.e., to verify that the jaundice is indeed posthepatic rather than hepatic), (2) to determine the level of the obstruction, (3) to identify the specific cause of the obstruction, and (4)

Infantile cholestatic syndromes
Inherited metabolic defects
No identifiable cause (idiopathic hepatic jaundice)

Hepatic Jaundice

Hepatic jaundice may be either acute or chronic and may be caused by a variety of conditions [see Table 2].

Acute hepatic jaundice may arise de novo or in the setting of ongoing liver disease. Historical clues may suggest a particular cause, such as medications or viral hepatitis. Physical examination usually reveals little. In the presence of preexisting chronic liver disease, bedside stigmata (e.g., ascites, spider nevi, caput medusae, palmar erythema, gynecomastia, or Dupuytren contracture) may be present. Although specific therapies exist for certain clinical problems (e.g., acetylcysteine for acetaminophen ingestion and penicillin plus silibinin for *Amanita phalloides* poisoning), treatment in most cases remains supportive. Patients in whom encephalopathy develops within 2 to 8 weeks of the onset of jaundice are usually classified as having fulminant hepatic failure. Evidence of encephalopathy, renal failure, or a severe coagulopathy is predictive of poor outcome in this setting.¹²⁶ The most common causes of fulminant hepatic failure are viral hepatitis and drug toxicity. The mortality from fulminant hepatic failure remains high even though liver transplantation has favorably affected the prognosis.¹²⁷

In cases of chronic hepatic jaundice, the patient may have chronic hepatitis or cholestasis, with or without cirrhosis. The cause usually is determined on the basis of the history in conjunction with the results of serology, biochemistry, viral DNA analysis, and, occasionally, histology. Causes include viral infection, drug-induced chronic hepatitis, autoimmune liver disease, genetic disorders (e.g., Wilson disease and α_1 -antitrypsin deficiency), chronic cholestatic disorders, alcoholic liver disease, and steatohepatitis.¹²⁸ Physical examination reveals the stigmata of chronic liver disease and occasionally suggests a specific cause (e.g., Kayser-Fleischer rings on slit-lamp examination in Wilson disease). Treatment, once again, is usually supportive, depending on the clinical presentation; whether more specific therapy is needed and what form it takes depend on the cause of liver disease. Although physiologic tests have been developed to quantify hepatic reserve, the most widely used and best-validated prognostic index remains the Child-Pugh classification (see below), which correlates with individual survival and has been shown to predict operative risk.¹²⁹ Liver transplantation is the treatment of choice in most cases of end-stage liver disease.

The Child-Pugh Classification¹²⁹ Numerical Score (points)

Variable	1	2	3
Encephalopathy	Nil (0)	Slight to moderate (1, 2)	Moderate to severe (3–5)
Ascites	Nil	Slight	Moderate to severe
Bilirubin, mg/dL (mmol/L*)	< 2 (< 34)	2–3 (34–51)	> 3 (> 51)
Albumin, g/dL (g/L*)	> 3.5 (> 35)	2.8–3.5 (28–35)	< 2.8 (< 28)
Prothrombin index	> 70%	40–70%	< 40%

Modified Child-Pugh risk grade (depending on total score): 5 or 6 points, grade A; 7 to 9 points, grade B; 10 to 15 points, grade C.

*Système International d'Unités, or SI units.

The Model for End-Stage Liver Disease (MELD) score is now used to prioritize the allocation of organs for liver transplantation by the United Network for Organ Sharing.¹³⁰ This score is based on the serum bilirubin and creatinine concentrations, the international normalized ratio (INR), and the presence of hepatocellular carcinoma; it does not make use of some of the more subjective components of the Child-Pugh score (e.g., ascites and encephalopathy).

to provide complementary information relating to the underlying diagnosis (e.g., staging information in cases of malignancy).

Of the many imaging methods available today, the gold standard for defining the level of a biliary obstruction before operation in a jaundiced patient remains direct cholangiography, which can be performed either via endoscopic retrograde cholangiopancreatography (ERCP) or via percutaneous transhepatic cholangiography (PTC). Unlike other imaging modalities, direct cholangiography poses significant risks to the patient: there is a 4 to 7% incidence of pancreatitis or cholangitis after ERCP,^{17,18} and there is a 4% incidence of bile leakage, cholangitis, or bleeding after PTC.¹⁹ There are also several risks that are particular to the manipulation of an obstructed biliary system (see below). For these reasons, the role of ERCP and PTC is increasingly a therapeutic one: therefore, it is important to gather as much imaging information as possible on the likely cause of the jaundice before performing either investigation.²⁰ We have found the following approach to be an efficacious, cost-effective,²¹ and safe way of obtaining such information in a patient with presumed posthepatic jaundice.

The presence of ductal dilatation of the intrahepatic or extrahepatic biliary system confirms that a posthepatic cause is responsible for the jaundice. Ultrasonography detects ductal dilatation with an accuracy of 95%, although the

results are to some extent operator dependent.²² If ultrasonography does not reveal bile duct dilatation, it is unlikely that an obstructing lesion is present. In some cases, even though ductal dilatation is absent, other ultrasonographic findings may still point to a specific hepatic cause of jaundice (e.g., cirrhosis or infiltration of the liver by tumor).

There are a few specific instances in which ultrasonography may fail to detect a posthepatic cause of jaundice. For instance, very early in the course of an obstructive process, not enough time may have elapsed for biliary dilatation to occur. In this setting, a hepatoinodiacetic acid (HIDA) scan has often helped identify bile duct blockage.²³ The yield from this test is highest when the serum bilirubin level is lower than 100 mmol/L.¹ Occasionally, the intrahepatic biliary tree is unable to dilate; possible causes of such inability include extensive hepatic fibrosis, cirrhosis, sclerosing cholangitis, and liver transplantation. If one of these diagnoses is suspected, ERCP, magnetic resonance cholangiopancreatography (MRCP), or PTC will eventually be required to confirm the diagnosis of biliary obstruction. Occasionally, the biliary tree dilatation may be intermittent; possible causes of this condition include choledocholithiasis and some biliary tumors. In a patient with gallstones, transient liver test abnormalities by themselves may suggest an intermediate to high likelihood of common bile duct (CBD) stones, even if there is no biliary ductal dilatation.^{24,25} If one of these diagnoses is

suspected, ultrasonography may be repeated after a short period of observation (when clinically applicable); biliary ductal dilatation then generally becomes apparent. If all of these unusual clinical situations have been ruled out, a hepatic cause for the jaundice should be sought [see Table 2] and a liver biopsy considered.^{26,27}

Besides being able to identify the presence of extrahepatic ductal obstruction with a high degree of reliability, ultrasonography can accurately determine the level of the obstruction in 90% of cases.²⁸ For example, a dilated gallbladder suggests that the obstruction is probably located in the middle third or the distal third of the CBD.

Some centers prefer computed tomography (CT) to ultrasonography as the initial imaging modality,²⁹ but we, like a number of other authors,³⁰ find ultrasonography to be the most expedient, least invasive, and most economical imaging method for differentiating between hepatic and posthepatic causes of jaundice, as well as for suggesting the level of obstruction.³¹ Traditional imaging techniques, such as oral or intravenous (IV) cholangiography, have a negligible role to play in this setting because of their very poor accuracy and safety, especially in jaundiced patients.

MRCP [see Figure 1] and endoscopic ultrasonography (EUS) have been used to visualize the biliary and pancreatic trees in various populations of patients with obstructive jaundice.^{32–36} Compared with direct cholangiography, both appear to be excellent at diagnosing biliary obstruction and establishing its location and nature.^{37,38} MRCP exhibits more modest detection rates when diagnosing small CBD stones.^{39,40} Spiral (helical) CT scanning is also useful in diagnosing biliary obstruction and determining its cause, although concomitant oral or IV cholangiography is required to detect choledocholithiasis.^{41–43}

In addition to their ability to detect choledocholithiasis, spiral CT, EUS, and MRCP in combination with abdominal magnetic resonance imaging (MRI) (e.g., of the pancreas) are very useful in diagnosing and staging biliopancreatic tumors.^{44–46} Cytology specimens are readily obtained via fine-needle aspiration (FNA) during CT or EUS.⁴⁵

It is our current practice to employ these modalities as second-line tests after the initial abdominal ultrasonographic examination. To obtain a diagnosis, we favor EUS for periampullary pathologic conditions and MRI with MRCP for more proximal diseases of the biliary tree.

In making the choice among the various available second-line tests, local expertise and cost-effectiveness become important considerations. Unfortunately, the reports on cost-effectiveness published to date have suffered either from limited assumptions (when the methodology involved decision modeling) or from the lack of an effectiveness-type design (when the methodology involved allocation of patients).

Workup and Management of Posthepatic Jaundice

Once ultrasonography has confirmed that ductal obstruction is present, there are three possible clinical scenarios:

Figure 1 Endoscopic retrograde cholangiopancreatography (a) and corresponding magnetic resonance cholangiopancreatography (b) demonstrate the presence of a stone in the distal common bile duct.

suspected cholangitis, suspected choledocholithiasis without cholangitis, and a suspected lesion other than choledocholithiasis. The direction of the subsequent workup depends on which of the three appears most likely.

SUSPECTED CHOLANGITIS

If a jaundiced patient exhibits a clinical picture compatible with acute suppurative cholangitis (Charcot triad),^{47,48} the most likely diagnosis is choledocholithiasis. After appropriate resuscitation, correction of any coagulopathies present, and administration of antibiotics, ERCP is indicated for diagnosis and treatment.⁴⁹ If ERCP is unavailable or is not feasible (e.g., because of previous Roux-en-Y reconstruction), trans-hepatic drainage or surgery may be necessary. It is important to emphasize here that the mainstay of treatment of severe cholangitis is not just the administration of appropriate antibiotics but rather the establishment of adequate biliary drainage.

SUSPECTED CHOLEDOCHOLITHIASIS WITHOUT CHOLANGITIS

Choledocholithiasis is the most common cause of biliary obstruction.^{12,13} It should be strongly suspected if the jaundice is episodic or painful or if ultrasonography has demonstrated the presence of gallstones or bile duct stones. Patients with suspected choledocholithiasis should be referred for laparoscopic cholecystectomy with either preoperative ERCP, intraoperative cholangiography, or intraoperative ultrasonography.⁵⁰ We favor preoperative ERCP in this setting of jaundice because its diagnostic yield is high,⁵¹ it allows confirmation of the diagnosis preoperatively (thus obviating intraoperative surprises), and it is capable of clearing the CBD of stones in 95% of cases. Decision analyses appear to confirm the utility of this strategy when laparoscopic CBD exploration is not an option.^{52–56} Many authors, however, favor a fully laparoscopic approach, in which choledocholithiasis is detected in the operating room by means of intraoperative cholangiography^{57,58} or ultrasonography^{59–61} and laparoscopic biliary clearance is performed when choledocholithiasis is confirmed. Given that both the ERCP approach and the fully laparoscopic approach have advantages and limitations, the optimal approach in a particular setting should be dictated by local expertise.

SUSPECTED LESION OTHER THAN CHOLEDOCHOLITHIASIS

If no gallstones are identified, if the clinical presentation is less acute (e.g., constant abdominal or back pain), or if there are associated constitutional symptoms (e.g., weight loss, fatigue, and long-standing anorexia), the presence of a lesion other than choledocholithiasis should be suspected. In such cases, another imaging modality besides the ultrasonography already performed must be considered before the decision is made to proceed to cholangiography or operation.

Possible causes of posthepatic obstruction (other than choledocholithiasis) may be classified into three categories, depending on the location of the obstructing lesion (as suggested by the pattern of gallbladder and biliary tree dilatation on the ultrasonogram): the upper third of the biliary tree, the middle third, or the lower (distal) third [see Table 3]. Once it has been determined that choledocholithiasis is unlikely, the

Table 3 Causes of Posthepatic Jaundice

Upper-third obstruction
Polycystic liver disease
Caroli disease
Hepatocellular carcinoma
Oriental cholangiohepatitis
Hepatic arterial thrombosis (e.g., after liver transplantation or chemotherapy)
Hemobilia (e.g., after biliary manipulation)
Iatrogenic bile duct injury (e.g., after laparoscopic cholecystectomy)
Cholangiocarcinoma (Klatskin tumor)
Sclerosing cholangitis
Papillomas of the bile duct
Middle-third obstruction
Cholangiocarcinoma
Sclerosing cholangitis
Papillomas of the bile duct
Gallbladder cancer
Choledochal cyst
Intrabiliary parasites
Mirizzi syndrome
Extrinsic nodal compression (e.g., from breast cancer or lymphoma)
Iatrogenic bile duct injury (e.g., after open cholecystectomy)
Cystic fibrosis
Benign idiopathic bile duct stricture
Lower-third obstruction
Cholangiocarcinoma
Sclerosing cholangitis
Papillomas of the bile duct
Pancreatic tumors
Ampullary tumors
Chronic pancreatitis
Sphincter of Oddi dysfunction
Papillary stenosis
Duodenal diverticula
Penetrating duodenal ulcer
Retroduodenal adenopathy (e.g., lymphoma, carcinoid)

most common cause of such obstruction is pancreatic cancer.^{12,13} In adults, many of the other possible causes also involve malignant processes. Consequently, the next step in the workup of the patient is typically the assessment of resectability and operability.

Diagnosis and Assessment of Resectability

Assessment of the resectability of a tumor usually hinges on whether the superior mesenteric vein, the portal vein, the superior mesenteric artery, and the porta hepatis are free of tumor and on whether there is evidence of significant local adenopathy or extrapancreatic extension of tumor. Unfortunately, the majority of lesions will be clearly unresectable, either because of tumor extension or because of the presence of hepatic or peritoneal metastases.

Many imaging modalities are currently used to determine resectability, and several of these have been established as effective alternatives to direct cholangiography because they involve little, if any, morbidity. Their accuracy varies according to the underlying pathology and the expertise of the user. They have been studied mostly with respect to the staging and diagnosis of pancreatic, periampullary, and biliary hilar cancers.

For determining resectability and staging lesions before operation, we rely mainly on spiral CT. The advent and

widespread availability of multidetector CT have made this modality the dominant second-line imaging method in cases of suspected pancreatic masses. For optimal evaluation of the pancreas, a fine-cut dual-phase (arterial phase and portal venous phase) scan should be obtained. Oral administration of water allows better evaluation of the duodenum and the ampulla.^{62,63} At present, spiral CT is considered to be superior for the diagnosis and staging of lesions such as pancreatic cancer.^{44,64,65} It exhibits a high negative predictive value and has a false positive rate of less than 10%; its sensitivity is optimal for pancreatic lesions larger than 1.5 cm in diameter. Ascites, liver metastases, lymph nodes larger than 2 cm in diameter, and invasion into adjacent organs are all signs of advanced disease.⁶⁶ On the basis of these criteria, spiral CT can predict that a lesion will not be resectable with an accuracy approaching 95%; however, as many as 33% of tumors that appear to be resectable on CT are found to be unresectable at operation.⁶⁵

MRI-based staging, along with MRCP, can further dictate the subsequent choice of therapy.^{66–69} MRI may be particularly useful for following up patients in whom clip artifacts interfere with a CT image.⁶⁶ It also appears to be successful in detecting cholangiocarcinoma spreading along the proximal biliary tree.⁷⁰ Given the renewed interest in biliary contrast media and the availability of software optimized for multidetector scanners, CT cholangiography may soon rival MRCP for evaluation of the biliary tree in cases of suspected malignancy.⁷¹

Only in a few very rare instances is traditional angiography used to assess resectability or stage a hepatobiliary or pancreatic neoplasm. Increasingly, it is being replaced by CT angiography or duplex Doppler ultrasonography, which can confirm the presence of flow in the hepatic arterial or portal venous systems and occasionally can demonstrate invasion of these vessels by tumor.⁷² Magnetic resonance angiography (MRA) has also been used, with excellent results. As yet, none of these noninvasive modalities have been shown to be clearly superior to any of the others.⁷³

EUS is a highly sensitive method of imaging the pancreas and the duodenum.^{45,74,75} In two large studies, it was found to be superior to CT and standard ultrasonography in staging pancreatic and ampullary cancers.^{76,77} Subsequent studies indicated that whereas EUS is superior to CT for detection and staging, it provides similar information regarding nodal status and overall assessment of resectability.^{62,78} From a cost-minimization point of view, the optimal strategy is to begin with a dual-phase CT scan and to follow up with EUS only in cases in which further information or a tissue diagnosis is required.^{79,80} In another large series, EUS was reported to be more accurate than CT in the comparative staging of pancreatic and ampullary cancers. It has also been found useful for identifying small (< 2 cm) pancreatic tumors, which may be suspected in a patient who has an obstruction of the distal third of the bile duct and whose CT scan is normal.⁷⁵ Furthermore, EUS is currently the dominant technique for staging ampullary tumors.⁸¹

In patients with a suspected pancreatic tumor, direct FNA of the lesion at the time of EUS has become the gold-standard method for obtaining a tissue diagnosis. In the case of potentially resectable lesions, however, this measure adds very little to the decision-making process. The limited data

currently available suggest that assays of tumor markers in serum and pancreatic fluid are useful, particularly for cystic lesions of the pancreas.⁸²

At this point in the evaluation, patients can be referred either for cholangiography (ERCP or MRCP) to clarify a still unclear diagnosis or for biliary decompression (see below). MRI of the pancreas with MRCP continues to improve rapidly. It is a noninvasive modality that evaluates the pancreas, vasculature, and pancreatobiliary ductal system in a single examination, with the additional benefit of avoiding ionizing radiation and iodinated contrast agents.⁸³ MRCP remains our test of choice for evaluation of middle- and upper-third lesions in cases in which decompression is not required.

In the event that none of these modalities point to a diagnosis, the use of ¹⁸F-fluorodeoxyglucose (FDG) positron emission tomography (PET) may be considered to help differentiate benign pancreatic conditions from malignant ones.^{84,85} Besides facilitating diagnosis, FDG-PET provides information regarding occult metastases and can be useful in detecting recurrent disease. Experience with FDG-PET is growing rapidly as this imaging modality becomes more readily accessible.

When a biliary stricture is detected at cholangiography, brush cytology or biopsy is mandatory. Biliary cytology, however, has been disappointing, particularly at ERCP: diagnostic accuracy ranges from 40 to 85%,^{86,87} mostly because the negative predictive value is poor. Accuracy improves with multiple sampling and when a biliary rather than a pancreatic malignancy is detected. In addition, biopsy tends to be more accurate than brush cytology.⁸⁶

Nonoperative Management: Drainage and Cholangiography

In the majority of patients with malignant obstructions, treatment is palliative rather than curative. It is therefore especially important to recognize and minimize the iatrogenic risks related to the manipulation of an obstructed biliary system; this is why staging and cholangiography are currently being performed with EUS and MRCP.

It is therefore especially important to recognize and minimize the iatrogenic risks related to the manipulation of an obstructed biliary system; this is why staging and cholangiography are currently being performed with EUS and MRCP.

Cholangiography and decompression of obstructed biliary system As a rule, we favor ERCP, although PTC may be preferable for obstructions near the hepatic duct bifurcation. Whichever imaging modality is used, the following four principles apply:

1. In the absence of preexisting or concomitant hepatocellular dysfunction, drainage of one half of the liver is generally sufficient for resolution of jaundice.⁸⁸
2. Because of its external diameter, a transhepatic drain, once inserted, does not necessarily permit equal drainage of all segments of the liver, particularly if there are a number of intrahepatic ductal stenoses. Accordingly, some patients with conditions such as sclerosing cholangitis or a growing tumor may experience persistent sepsis from an infected

excluded liver segment even when the prosthesis is patent [see Figure 2]. An excluded segment may even be responsible for severe persistent pruritus.

3. Any attempt at opacifying an obstructed biliary tree introduces a significant risk of subsequent cholangitis, even when appropriate antibiotic prophylaxis is provided. Accordingly, when one elects to perform direct cholangiography, there should be a plan for biliary drainage either at the time of ERCP or PTC or soon thereafter.
4. Even though jaundice is believed to be associated with multiple adverse systemic effects (e.g., renal failure, sepsis, and impaired wound healing),^{89,90} routine preoperative drainage of an obstructed biliary system does not benefit patients who will soon undergo resection.^{91,92} A growing body of evidence suggests that in patients with either pancreatic^{93,94} or hepatic⁹⁵ malignancies, routine preoperative direct cholangiography with decompression is associated with a higher incidence of postoperative complications when tumor resection is ultimately carried out.

When direct cholangiography is ordered, it should be thought of as more than just a diagnostic test: it is the ideal setting for cytology, biopsy, or even drainage of the obstructed bile duct via a sphincterotomy, a nasobiliary tube, or a catheter or stent. Accordingly, it is essential that the surgeon, the gastroenterologist, and the radiologist discuss the possible need for drainage well before it is required. Early, open communication among all members of the treating team is a hallmark of the modern management of biliary obstruction.

Palliation in patients with advanced malignant disease

When a patient has advanced malignant disease, drainage of the biliary system for palliation is not routinely indicated, because the risk of complications related to the procedure may outweigh the potential benefit. Indeed, the best treatment for a patient with asymptomatic obstructive jaundice and liver metastases may be supportive care alone.⁹⁶ Biliary decompression is indicated if cholangitis or severe pruritus interferes with quality of life.

We, like others,²¹ consider a stent placed with ERCP to be the palliative modality of choice for advanced disease, although upper-third lesions may be managed most easily through the initial placement of an internal or external catheter at the time of PTC. Metal expandable stents remain patent longer than large conventional plastic stents^{97,98} and are becoming the standard of care.^{99,100} Whether plastic biliary stents should be replaced prophylactically or only after obstruction has occurred remains controversial; however, results from a randomized, controlled trial (RCT) favor the former approach.¹⁰¹ In another RCT, the use of prophylactic ciprofloxacin did not prolong stent patency but did reduce the incidence of cholangitis and improve quality-of-life scores.¹⁰²

RCTs suggest that surgical biliary bypass should be reserved for patients who are expected to survive for 6 months or longer because bypass is associated with more prolonged palliation at the cost of greater initial morbidity.¹⁰³

The role of prophylactic gastric drainage at the time of operative biliary drainage remains controversial,^{104,105} although two RCTs demonstrated a reduced incidence of subsequent clinical gastric outlet obstruction when this measure was employed. Jaundiced patients with unresectable lesions who also present with duodenal or jejunal obstruction should be referred for gastrojejunostomy at the time of biliary bypass surgery. There is evidence to suggest that when a pancreatic malignancy is present, intraoperative celiac ganglion injection should be performed for either prophylactic or therapeutic pain control.¹⁰⁶

Operative Management at Specific Sites: Bypass and Resection

Surgical treatment of tumors causing biliary obstruction is determined primarily by the level of the biliary obstruction.

Figure 2 (a) Endoscopic retrograde cholangiopancreatography demonstrates missing liver segments. (b) Transhepatic cholangiography of segment 6 reveals the excluded liver ductal system. (c) Magnetic resonance cholangiopancreatography shows the excluded liver segments, as well as the biliary system, which still communicates with the common hepatic duct.

Current evidence indicates that modern surgical approaches are resulting in lower postoperative morbidity and, possibly, improved 5-year survival¹⁰⁷; however, the prognosis is still uniformly poor, except for patients with ampullary tumors. In fact, the surgical procedure rarely proves curative, even after meticulous preoperative patient selection.

At one time, there was considerable enthusiasm for routine use of staging laparoscopy; at present, however, selective use is recommended.¹⁰⁸ The benefits of staging laparoscopy include more accurate assessment of resectability and prevention of the prolonged hospital stay and convalescence associated with an unnecessary laparotomy. Laparoscopy is used mostly to detect peritoneal carcinomatosis, liver metastases, malignant ascites, and gross hilar adenopathy.^{109,110} The main limitation of laparoscopy in this setting appears to be that it does not accurately detect the spread of tumors to lymph nodes or the vascular system.¹¹¹ In several studies, a combined approach that included both laparoscopy and laparoscopic ultrasonography was associated with shorter hospital stays and lower costs.^{108,110–112}

In what follows, only the general principles of resection or bypass at each level of obstruction are discussed; operative technical details are addressed elsewhere. Our preferred method of biliary anastomosis, for either reconstruction or bypass, involves the fashioning of a Roux-en-Y loop, followed by a mucosa-to-mucosa anastomosis. In all cases, a cholecystectomy is performed to facilitate access to the biliary tree.

Upper-third obstruction

Palliation Because the left hepatic duct has a long extrahepatic segment that makes it more accessible, the preferred

bypass technique for an obstructing upper-third lesion is a left (or segment 3) hepaticojejunostomy. This operation has superseded the Longmire procedure because it does not involve formal resection of liver parenchyma. Laparoscopic bypass techniques that make use of segment 3 have been developed, but their performance has yet to be formally assessed, and they cannot yet be incorporated into a management algorithm.^{113,114}

Resection for cure The hilar plate is taken down to lengthen the hepatic duct segment available for subsequent anastomosis. Often a formal hepatectomy or segmentectomy is required to ensure an adequate proximal margin of resection. If the resection must be carried out proximal to the hepatic duct bifurcation, several choledochojejunostomies will have to be done to anastomose individual hepatic biliary branches. Frozen-section examination of the proximal and distal resection margins is important because of the propensity of tumors such as cholangiocarcinoma to spread in a submucosal or perineural plane.

The results of aggressive hilar tumor resections that included as much liver tissue as was necessary to obtain a negative margin appear to justify this approach.¹¹⁵ In cases of left hepatic involvement, resection of the caudate lobe (segments 1 and 9) is indicated as well.^{116,117}

Middle-third obstruction

Palliation Surgical bypass of middle-third lesions is technically simpler because a hepaticojejunostomy can often be performed distal to the

hepatic duct bifurcation, which means that exposure of the hilar plate or the intrahepatic ducts is unnecessary.

Resection for cure Discrete tumors in this part of the bile duct, although uncommon, are usually quite amenable to resection along with the lymphatic chains in the porta hepatis. Resection of an early gallbladder cancer may, on occasion, necessitate the concomitant resection of segment 5, although the value of resecting this segment prophylactically has not been conclusively demonstrated.¹¹⁸ Sometimes jaundice from a suspected middle-third lesion is, in fact, caused by a case of Mirizzi syndrome [see Figure 3]. In such cases, a gallstone is responsible for extrinsic obstruction of the CBD, either by causing inflammation of the gallbladder wall or via direct impingement. Proper treatment of this syndrome may involve hepaticojejunostomy in addition to cholecystectomy if a cholecystocholedochal fistula is present.¹¹⁹

Figure 3 Endoscopic retrograde cholangiopancreatography demonstrates extrinsic compression of the common hepatic duct by a stone in the Hartmann pouch. A biliary stent has been inserted for drainage.

Lower-third obstruction

Palliation The preferred bypass technique for lower-third lesions is a Roux-en-Y choledochojejunostomy. Cholecystojejunostomy carries a

higher risk of complications and subsequent development of jaundice¹²⁰; this remains true even when it is performed laparoscopically. Occasionally, it may be done as a temporizing measure before a more definitive procedure in the context of an upcoming transfer to a specialized center.

Resection for cure Occasionally, an impacted CBD stone at the duodenal ampulla mimics a tumor and is not clearly identified preoperatively. Because of the growing use of EUS and MRCP, such a situation is increasingly uncommon. Resection of a lower-third lesion usually involves a pancreaticoduodenectomy, although transduodenal ampullary resection may be an acceptable alternative for a small adenoma of the ampulla; local duodenal resection without removal of the head of the pancreas has also been described.¹²¹ For optimal results, pancreaticoduodenectomy is best performed in specialized centers.¹²²

It has been suggested that postoperative adjuvant therapy may improve the prognosis after resection of a pancreatic adenocarcinoma,¹⁰⁷ but this debate falls outside the scope of our discussion.

Postoperative Jaundice

A clinical scenario of particular pertinence to surgeons that we have not yet addressed is the development of jaundice in the postoperative setting.

Jaundice develops in approximately 1% of all surgical patients after operation.¹²³ When jaundice occurs after a hepatobiliary procedure, it may be attributable to specific biliary causes, such as retained CBD stones, postoperative biliary leakage (through reabsorption of bile leaking into the peritoneum) [see Figure 4], injury to the CBD, and the subsequent development of biliary strictures. In most instances, however, the jaundice derives from a combination of disease processes, and only rarely is invasive testing or active treatment required.¹²⁴

A diagnostic approach similar to the one outlined earlier (see above) is applicable to postoperative jaundice. However, as the possible causes of postoperative jaundice vary depending on the time interval between the operation and the development of jaundice, the following diagnostic approach may also be useful:

- Jaundice may develop within 48 hours of the operation; this is most often the result of the breakdown of red blood cells, occurring in the context of multiple blood transfusions (particularly with stored blood), the resorption of a large hematoma, or a transfusion reaction. Hemolysis may also develop in a patient with a known underlying hemolytic anemia and may be precipitated by the administration of specific drugs (e.g., sulfa drugs in a patient who has glucose-6-phosphate dehydrogenase deficiency).¹²⁵ Cardiopulmonary bypass or the insertion of a prosthetic

Figure 4 Jaundice has occurred after laparoscopic cholecystectomy as a result of bile leakage from a distal biliary tributary. A stent has been inserted to decrease bile duct luminal pressure and foster spontaneous resolution.

valve may be associated with the development of early postoperative jaundice as well. Gilbert syndrome [see Sidebar Hepatic Jaundice] may first manifest itself early in the postoperative period. Occasionally, a mild conjugated hyperbilirubinemia may be related to Dubin-Johnson syndrome, which is an inherited disorder of bilirubin metabolism. This condition is usually self-limited and is characterized by the presence of a melaninlike pigment in the liver.

- Intraoperative hypotension or hypoxemia or the early development of heart failure can lead to conjugated hyperbilirubinemia within 5 to 10 days after operation. The hyperbilirubinemia may be associated with other end-organ damage (e.g., acute tubular necrosis). In fact, any impairment of renal function causes a decrease in bilirubin excretion and can be responsible for a mild hyperbilirubinemia.
- Jaundice may develop 7 to 10 days after operation in association with a medication-induced hepatitis attributable to an anesthetic agent. This syndrome has an estimated incidence of 1 in 10,000 after an initial exposure.¹²⁵ More commonly, the jaundice is related to the administration of antibiotics or other medications used in the perioperative setting.¹²⁵

- After the first week, jaundice associated with intrahepatic cholestasis is often a manifestation of a septic response and usually presents in the setting of overt infection, particularly in patients with multiple organ dysfunction syndrome. Gram-negative sepsis from an intra-abdominal source is typical; if it persists, the outcome is likely to be poor. Jaundice may occur in as many as 30% of patients receiving total parenteral nutrition (TPN). It may be attributable to steatosis, particularly with formulas containing large amounts of carbohydrates. In addition, decreased export of bilirubin from the hepatocytes may lead to cholestasis, the severity of which appears to be related to the duration of TPN administration. Acalculous cholecystitis or even ductal obstruction may develop as a result of sludge in the gallbladder and the CBD. An elevated postoperative bilirubin level at any time may also result from unsuspected hepatic or posthepatic causes (e.g., occult cirrhosis, choledocholithiasis, or cholecystitis). A rare cause of postoperative jaundice is the development of thyrotoxicosis.

Another entity to consider (as a diagnosis of exclusion) is so-called benign postoperative cholestasis, a primarily cholestatic, self-limited process with no clearly demonstrable cause that typically arises within 2 to 10 days after operation. Benign postoperative cholestasis may be attributable to a combination of mechanisms, including an increased pigment load, impaired liver function resulting from hypoxemia and hypotension, and decreased renal bilirubin excretion caused by varying degrees of tubular necrosis.¹²⁶ The predominantly conjugated hyperbilirubinemia may reach 40 mg/dL and remain elevated for as long as 3 weeks.¹²⁵

- In the late postoperative period, the development of non-A, non-B, non-C viral hepatitis after transfusion of blood products will usually occur within 5 to 12 weeks of operation.

4 INTESTINAL OBSTRUCTION

Fuad Alkhoury, MD, and W. Scott Helton, MD, FACS

Intestinal obstruction is a common medical problem and accounts for a large percentage of surgical admissions for acute abdominal pain [see 5:1 *Acute Abdominal Pain*].¹ It develops when air and secretions are prevented from passing aborally as a result of either intrinsic or extrinsic compression (i.e., mechanical obstruction) or gastrointestinal (GI) paralysis (i.e., nonmechanical obstruction in the form of ileus or pseudo-obstruction). Small intestinal ileus is the most common form of intestinal obstruction; it occurs after most abdominal operations and is a common response to acute extra-abdominal medical conditions and intra-abdominal inflammatory conditions [see Table 1].² Mechanical small bowel obstruction is somewhat less common; such obstruction is secondary to intra-abdominal adhesions, hernias, or cancer in about 90% of cases [see Table 2]. Mechanical colonic obstruction accounts for only 10 to 15% of all cases of mechanical obstruction and most often develops in response to obstructing carcinoma, diverticulitis, or volvulus [see Table 3]. Acute colonic pseudo-obstruction occurs most frequently in the postoperative period or in response to another acute medical illness.

There are several different methods of classifying mechanical obstruction: acute versus chronic, partial versus complete, simple versus closed loop, and gangrenous versus nongangrenous. The importance of these classifications is that the natural history of the condition, its response to treatment, and the associated morbidity and mortality all vary according to which type of obstruction is present.

When chyme and gas can traverse the point of obstruction, obstruction is partial; when this is not the case, obstruction is complete. When the bowel is occluded at a single point along the intestinal tract, leading to intestinal dilatation, hypersecretion, and bacterial overgrowth proximal to the obstruction and decompression distal to the obstruction, simple obstruction is present. When a segment of bowel is occluded at two points along its course by a single constrictive lesion that occludes both the proximal and the distal end of the intestinal loop and traps the bowel's mesentery, closed-loop obstruction is present. When the blood supply to a closed-loop segment of bowel becomes compromised, leading to ischemia and eventually to bowel wall necrosis and perforation, strangulation is present. The most common causes of simple obstruction are intra-abdominal adhesions, tumors, and strictures; the most common causes of closed-loop obstruction are hernias, adhesions, and volvulus.

One of the most difficult tasks in general surgery is deciding when to operate on a patient with intestinal obstruction. The purpose of the following discussion is to outline a safe, efficient, and cost-effective stepwise approach to making this often difficult decision and to optimizing the management of patients with this problem. Absolutes are few and far between: treatment must always be highly individualized. Consequently, the

following recommendations are intended only as guidelines, not as surgical dicta.

Clinical Evaluation

HISTORY AND CLINICAL SETTING

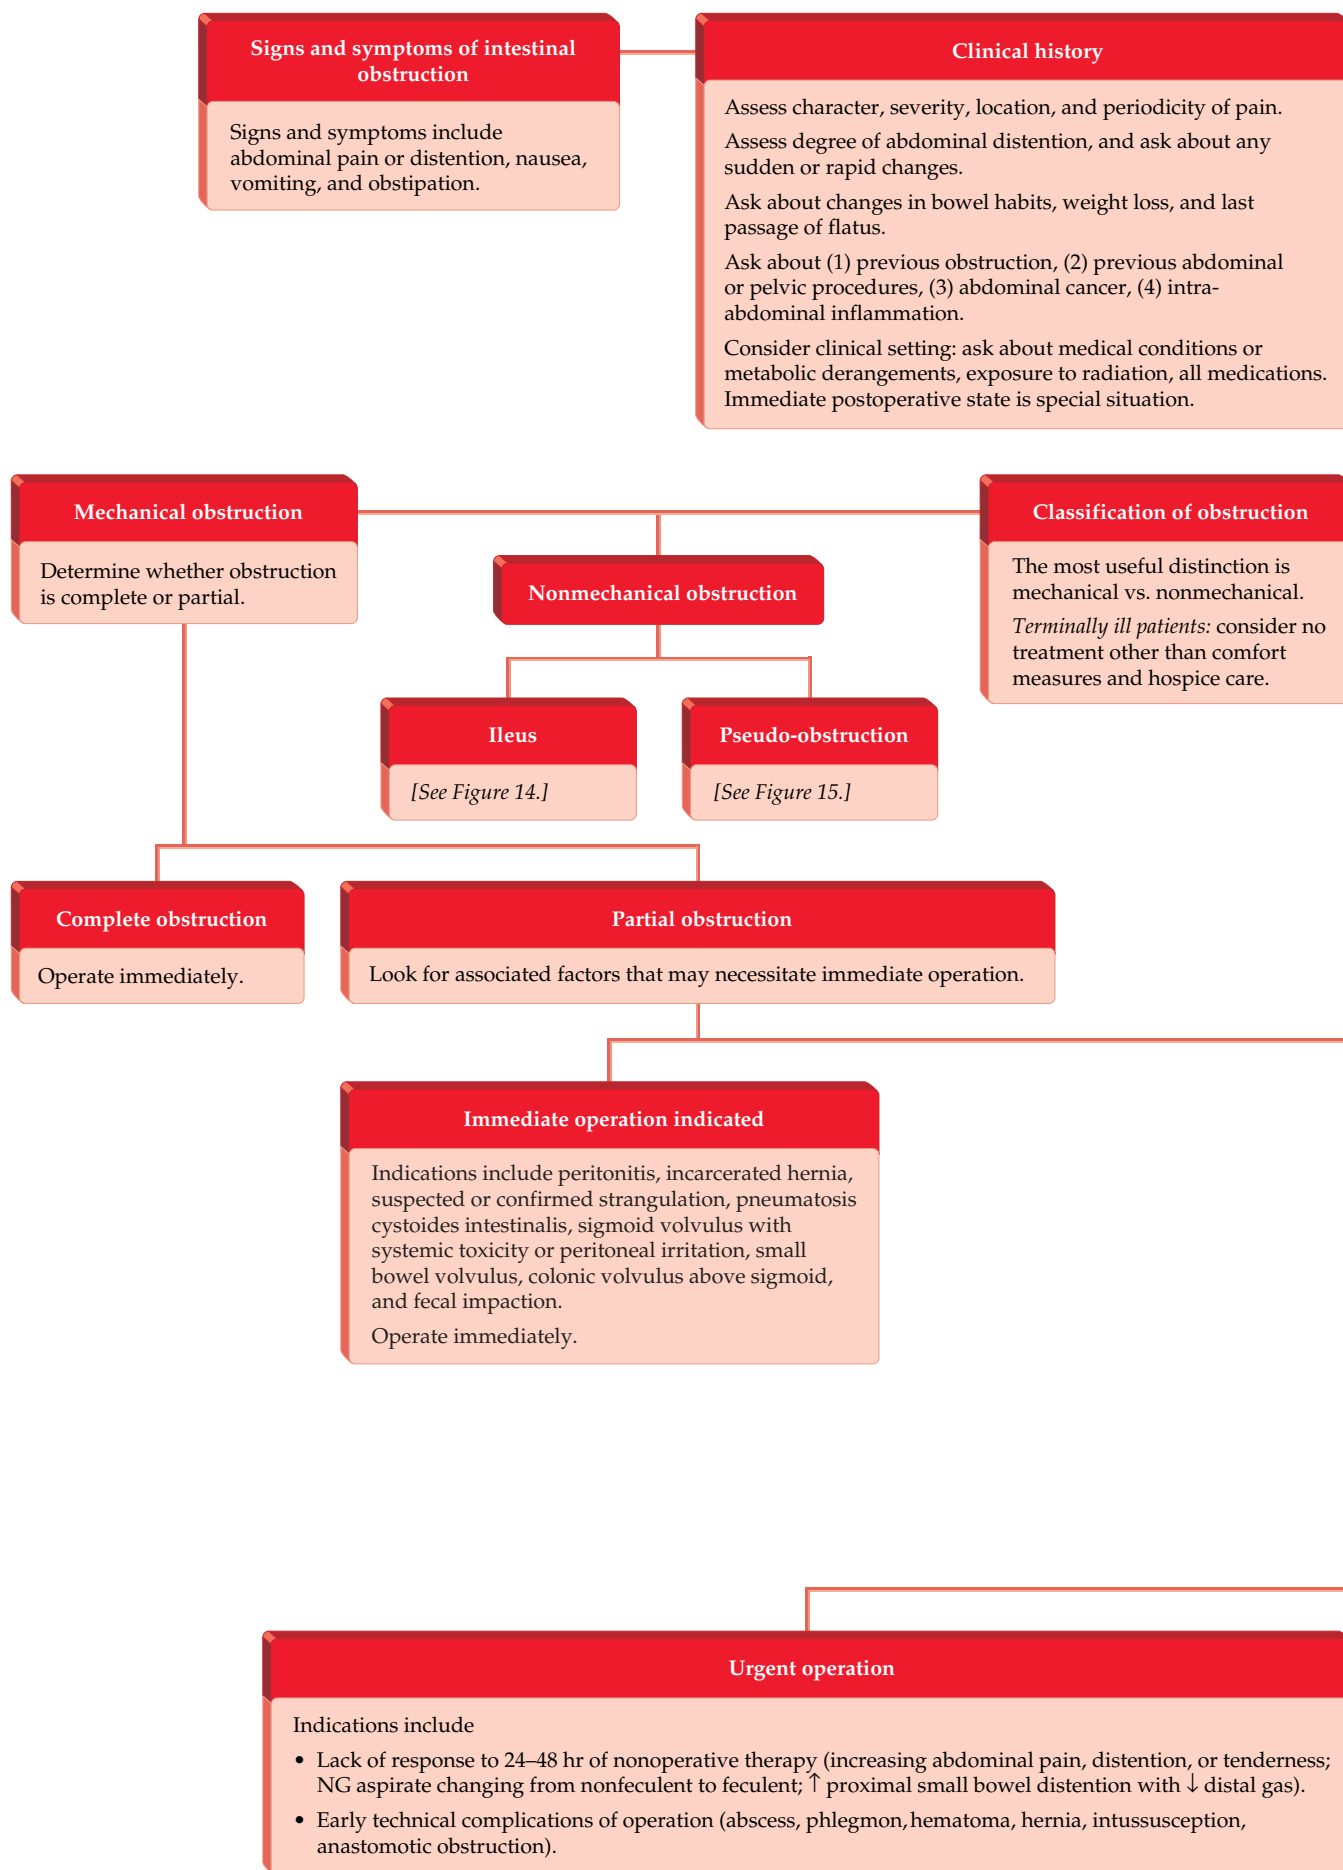

When a patient complains of acute obstipation, abdominal pain and distention, nausea, and vomiting, the probability that either mechanical bowel obstruction or ileus is present is very high.³ Mechanical obstruction can often be distinguished from ileus or pseudo-obstruction on the basis of the location, character, and severity of abdominal pain. Pain from mechanical obstruction is usually located in the middle of the abdomen, whereas pain from ileus and pseudo-obstruction is diffuse. Pain from ileus is usually mild, and pain from obstruction is typically more severe. In general, pain increases in severity and depth over time as obstruction progresses; however, in mechanical obstruction, pain severity may decrease over time as a result of bowel fatigue and atony. The periodicity of pain can help localize the level of obstruction: pain from proximal intestinal obstruction has a short periodicity (3 to 4 minutes), and distal small bowel or colonic pain has longer intervals (15 to 20 minutes) between episodes of nausea, cramping, and vomiting.

Abdominal distention, nausea, and vomiting usually develop after pain has already been felt for some time. The patient should be asked what degree of abdominal distention is present and whether there has been a sudden or rapid change. Distention developing over many weeks suggests a chronic process or progressive partial obstruction. Massive abdominal distention coupled with minimal crampy pain, nausea, and vomiting suggests long-standing intermittent mechanical obstruction or some form of chronic intestinal pseudo-obstruction. The combination of a gradual change in bowel habits, progressive abdominal distention, early satiety, mild crampy pain after meals, and weight loss also suggests chronic partial mechanical bowel obstruction. If the patient has undergone evaluation for similar symptoms before, any previous abdominal radiographs or contrast studies should be reviewed. The patient should be asked when flatus was last passed: failure to pass flatus may signal a transition from partial to complete bowel obstruction. Patients with an intestinal stoma (ileostomy or colostomy) who present with signs and symptoms of obstruction often report abdominal distention and pain after a sudden change in stomal output of stool, liquid, or air.

The patient should also be asked about (1) previous episodes of bowel obstruction, (2) previous abdominal or pelvic

Assessment of Intestinal Obstruction

Physical exam and resuscitate as necessary

Develop gestalt of patient's illness, and assess patient's vital signs, hydration, and cardiopulmonary system.

Place NG tube, Foley catheter, and IV. line immediately.

Assess volume and character of NG aspirate, and measure urine output.

Replace lost fluid with isotonic saline or lactated Ringer solution.

Look for signs of abscess, pneumonia, or myocardial infarction, and be alert for dyspnea, labored breathing, or jaundice.

Perform systematic abdominal examination: observation → auscultation → palpation and percussion. Look for abdominal masses, tenderness, incisions, and hernias; assess bowel sounds; examine rectum for masses, fecal impaction, and occult blood.

Investigative studies

Obtain chest x-rays and abdominal films.

If uncertainty about presence or nature of colonic obstruction remains, perform sigmoidoscopy and barium enema examination.

Measure serum electrolytes and creatinine, determine hematocrit, and order coagulation profile. If ileus is suspected, measure serum magnesium and calcium and order urinalysis.

Perform CT (with oral or IV contrast agents), fast MRI, or abdominal ultrasonography.

Immediate operation not indicated

Manage initially with nonoperative measures.

Reassess patient every 4 hr.

For partial obstruction, administer oral diatrizoate meglumine.

Look for changes in pain, abdominal findings, and volume and character of NG aspirate.

Repeat abdominal x-rays, and look for changes in gas distribution, pneumatosis cystoides intestinalis, and free intraperitoneal air.

Classify patient's condition as improved, unchanged, or worse.

Decide whether operative treatment is necessary and, if so, whether it should be done on urgent or elective basis.

Arrival of contrast agent in right colon within 24 hr is highly predictive of successful resolution of adhesive obstruction without operation.

No operation

Conditions that typically resolve with nonoperative therapy include adhesive obstruction (unless it does not improve in 12 hr), early postoperative obstruction (unless it does not improve in 2 wk), and various inflammatory conditions (IBD, radiation enteritis, diverticulitis, acute Crohn disease).

Elective operation

Indications include nontoxic, nontender sigmoid volvulus with sigmoidoscopically managed obstruction; recurrent adhesive or stricture-related small bowel obstruction; partial colonic obstruction unresponsive to 24 hr of nonoperative therapy; development and resolution of small bowel obstruction in patient who has never undergone abdominal operation.

Table 1 Causes of Ileus

Intra-abdominal causes
Intraperitoneal problems
Peritonitis or abscess
Inflammatory condition
Mechanical: operation, foreign body
Chemical: gastric juice, bile, blood
Autoimmune: serositis, vasculitis
Intestinal ischemia: arterial or venous, sickle cell disease
Retroperitoneal problems
Pancreatitis
Retroperitoneal hematoma
Spine fracture
Aortic operation
Renal colic
Pyelonephritis
Metastasis
Extra-abdominal causes
Thoracic problems
Myocardial infarction
Pneumonia
Congestive heart failure
Rib fractures
Metabolic abnormalities
Electrolyte imbalance (e.g., hypokalemia)
Sepsis
Lead poisoning
Porphyria
Hypothyroidism
Hypoparathyroidism
Uremia
Medicines
Opiates
Anticholinergics
Alpha agonists
Antihistamines
Catecholamines
Spinal cord injury or operations
Head, thoracic, or retroperitoneal trauma
Chemotherapy, radiation therapy

Table 2 Causes of Small Bowel Obstruction in Adults

Extrinsic causes
Adhesions*
Hernias (external, internal [paraduodenal], incisional)*
Metastatic cancer*
Volvulus
Intra-abdominal abscess
Intra-abdominal hematoma
Pancreatic pseudocyst
Intra-abdominal drains
Tight fascial opening at stoma
Intraluminal causes
Tumors*
Gallstones
Foreign body
Worms
Bezoars
Intramural abnormalities
Tumors
Strictures
Hematoma
Intussusception[see Figure 3]
Regional enteritis
Radiation enteritis

*Approximately 85% of all small bowel obstructions are secondary to adhesions, hernias, or tumors.

Table 3 Causes of Colonic Obstruction

Common causes
Cancer (primary, anastomotic, metastatic)
Volvulus
Diverticulitis
Pseudo-obstruction
Hernia
Anastomotic stricture
Unusual causes
Intussusception
Fecal impaction
Strictures (from one of the following)
Inflammatory bowel disease
Endometriosis
Radiation therapy
Ischemia
Foreign body
Extrinsic compression by a mass
Pancreatic pseudocyst
Hematoma
Metastasis
Primary tumors

operations, (3) a history of abdominal cancer, and (4) a history of intra-abdominal inflammation (e.g., inflammatory bowel disease, cholecystitis, pancreatitis, pelvic inflammatory disease, or abdominal trauma). Any of these factors increases the chance that the obstruction is secondary to an adhesion or recurrent cancer. Obstructive symptoms that come and go suddenly over several days in a patient older than 65 years should increase the index of suspicion for gallstone ileus.⁴ If the patient has experienced episodes of obstruction before, one should ask about the etiology and the response to treatment. If the patient has ever undergone an abdominal operation, one should try to obtain and read the operative report, which can provide a great deal of helpful information (e.g., description of adhesions, assessment of their severity, and evaluation of intra-abdominal pathology and anatomy). If abdominal cancer was present, one should find out what operation was performed and attempt to determine the likelihood of intra-abdominal recurrence.

The clinical setting often provides clues to the cause and type of bowel obstruction. In hospitalized patients, there is likely to be an associated medical condition or metabolic derangement that led to obstruction. A thorough review of the patient's medical history and hospital course should be undertaken to identify precipitating events that could have led to intestinal obstipation. One should ask the patient about any previous abdominal irradiation and should note and take into account all medications the patient is taking, especially anticoagulants and agents with anticholinergic side effects. Patients who are receiving chemotherapy or have undergone abdominal radiation therapy are prone to ileus. Severe infection, fluid and electrolyte imbalances, narcotic and anticholinergic medications, and intra-abdominal inflammation of any origin may be implicated. Acute massive abdominal distention in a hospitalized patient usually results from acute gastric distention, small bowel ileus, or acute colonic pseudo-obstruction. Excessive anticoagulation can lead to retroperitoneal, intra-abdominal, or intramural hematoma that can cause mechanical obstruction or ileus. Finally, there are specific problems that tend to arise in the postoperative period; these are discussed more fully elsewhere [see Urgent

Operation, Early Postoperative Technical Complications, No Operation, and Early Postoperative Obstruction, *below*].

PHYSICAL EXAMINATION AND RESUSCITATION

The initial steps in the physical examination are (1) developing a gestalt of the patient's illness and (2) assessing the patient's vital signs, hydration status, and cardiopulmonary system. A nasogastric tube, a Foley catheter, and an intravenous (IV) line are placed immediately while the physical examination is in progress. The volume and character of the gastric aspirate and urine are noted. A clear, gastric effluent is suggestive of gastric outlet obstruction. A bilious, nonfeculent aspirate is a typical sign of medial to proximal small bowel obstruction or colonic obstruction with a competent ileocecal valve. A feculent aspirate is a typical sign of distal small bowel obstruction. Volume replacement, if necessary, is initiated with isotonic saline solution or lactated Ringer solution. Urine output must be adequate (at least 0.5 mL/kg/hr) before the patient can be taken to the operating room (OR); supplemental potassium chloride (40 mEq/L) is administered once this is achieved.

Fever may be present, suggesting that the obstruction may be a manifestation of an intra-abdominal abscess. Signs of pneumonia or myocardial infarction should be sought: these conditions, like intestinal obstruction, can have upper abdominal pain, distention, nausea, and vomiting as presenting symptoms. Dyspnea and labored breathing may occur secondary to severe abdominal distention or pain, in which case, immediate relief should be provided by placing the patient in the lateral decubitus position and offering narcotics as soon as the initial physical examination is performed. Jaundice raises the possibility of gallstone ileus or metastatic cancer.

Examination of the abdomen proceeds in an orderly manner from observation to auscultation to palpation and percussion. The patient is placed in the supine position with the legs flexed at the hip to decrease tension on the rectus muscles. The degree of abdominal distention observed varies, depending on the level of obstruction: proximal obstructions may cause little or no distention. Abdominal scars should be noted. Abdominal asymmetry or a protruding mass suggests an underlying malignancy, an abscess, or closed-loop obstruction. The abdominal wall should be observed for evidence of peristaltic waves, which are indicative of acute small bowel obstruction.

Auscultation should be performed for at least 3 to 4 minutes to determine the presence and quality of bowel sounds. High-pitched bowel tones, tingles, and rushes are suggestive of an obstructive process, especially when temporally associated with waves of crampy pain, nausea, or vomiting. The absence of bowel tones is typical of intestinal paralysis but may also indicate intestinal fatigue from long-standing obstruction, closed-loop obstruction, or pseudo-obstruction.

Approximately 70% of patients with bowel obstruction have symmetrical tenderness, whereas fewer than 50% have rebound tenderness, guarding, or rigidity.³ The traditional teaching is that localized tenderness and guarding indicate underlying strangulated bowel; however, prospective studies have demonstrated that these physical findings are neither specific nor sensitive

for detecting underlying strangulation⁵ or even obstruction.³ Nevertheless, most surgeons still believe that guarding, rebound tenderness, and localized tenderness reflect underlying strangulation and therefore are indications for operation. Patients with ileus tend to have generalized abdominal tenderness that cannot be distinguished from the tenderness of mechanical obstruction. Gentle percussion is performed over all quadrants of the abdomen to search for areas of dullness (suggestive of an underlying mass), tympany (suggestive of underlying distended bowel), and peritoneal irritation.

A thorough search is made for inguinal, femoral, umbilical, and incisional hernias. The rectum is examined for masses, fecal impaction, and occult blood. If the patient has an ileostomy or a colostomy, the stoma is examined digitally to make sure that there is no obstruction at the level of the fascia.

Investigative Studies

IMAGING

One should obtain a chest x-ray in all patients with bowel obstruction to exclude a pneumonic process and to look for subdiaphragmatic air. In most cases, supine, upright, or lateral decubitus films of the abdomen can distinguish the type of obstruction present (mechanical or nonmechanical, partial or complete) and establish the location of the obstruction (stomach, small bowel, or colon). A useful technique for evaluating abdominal radiographs is to look systematically for intestinal gas along the normal route of the GI tract, beginning at the stomach, continuing through the small bowel, and, finally, following the course of the colon to the rectum. The following questions should be kept in mind as this is done:

- Are there abnormally dilated loops of bowel, signs of small bowel dilatation, or air-fluid levels?
- Are air-fluid levels and bowel loops in the same place on supine and upright films?
- Is there gas throughout the entire length of the colon (suggestive of ileus or partial mechanical obstruction)?
- Is there a paucity of distal colonic gas or an abrupt cutoff of colonic gas with proximal colonic distention and air-fluid levels (suggestive of complete or near-complete colonic obstruction)?
- Is there evidence of strangulation (e.g., thickened small bowel loops, mucosal thumb printing, pneumatosis cystoides intestinalis, or free peritoneal air)?
- Is there massive distention of the colon, especially of the cecum or sigmoid (suggestive of either volvulus or pseudo-obstruction)?
- Are there any biliary or renal calculi, and is there any air in the biliary tree (suggestive of gallstone ileus⁶ or a renal stone that could be causing ileus)?

It is important to be able to distinguish between small and large bowel gas. Gas in a distended small bowel outlines the valvulae conniventes, which traverse the entire diameter of the bowel lumen [see Figure 1]. Gas in a distended colon, on the other hand, outlines the colonic haustral markings, which cross only part of the bowel lumen and typically interdigitate

Figure 1 Supine radiograph from a patient with complete small bowel obstruction shows distended small bowel loops in the central abdomen with prominent valvulae conniventes (small white arrow). The bowel wall between the loops is thickened and edematous (large white arrow). No air is seen in the colon or the rectum. Note the presence of an isolated small bowel loop in the right lower quadrant (black arrow), which is seen fixed in the same location on upright films, as shown in Figure 4.

[see Figure 2 and Figure 3]. Distended small bowel loops usually occupy the central abdomen [see Figure 1], whereas distended large bowel loops are typically seen around the periphery [see Figure 2]. In patients with ileus, distention usually extends uniformly throughout the stomach, the small bowel, and the colon [see Figure 3], and air-fluid levels may be found in the colon and the small intestine.

Patients with gastric outlet obstruction or gastric atony typically have a giant gastric bubble if no nasogastric tube has been placed, with little or no air in the small bowel or the colon. Patients with mechanical small bowel obstruction usually have multiple air-fluid levels, with distended bowel loops of varying sizes arranged in an inverted U configuration [see Figure 4]. A dilated loop of small bowel appearing in the same location on supine and upright films suggests obstruction of a fixed segment of bowel by an adhesion or an internal hernia [see Figure 1 and Figure 4]. Small bowel obstruction is often accompanied by a paucity of gas in the colon. The complete absence of colonic gas is strongly suggestive of complete small bowel obstruction; however, the presence of colonic gas

Figure 2 Radiograph from a patient with acute colonic pseudo-obstruction shows a dilated colon with haustral markings (white arrow) and edematous small bowel loops (black arrow). Air extends down to the distal sigmoid. This picture is also consistent with rectal obstruction, which could have been excluded by rigid sigmoidoscopy.

does not exclude complete small bowel obstruction in that there may have been unevacuated gas distal to a point of complete obstruction before the radiograph was taken. On the other hand, if repeat radiographs demonstrate decreased or absent colonic or rectal gas in a patient with small bowel obstruction who previously had more colonic or rectal gas, it is probable that partial obstruction has become complete, and immediate operation is almost always indicated. High-grade obstruction of the colon with an incompetent ileocecal valve may manifest itself as distended small bowel loops with air-fluid levels, thereby mimicking small bowel obstruction. Hence, it is sometimes necessary to perform a barium enema to exclude colonic obstruction.

Massive gaseous distention of the colon is usually secondary to distal colonic or rectal obstruction, volvulus, or pseudo-obstruction [see Figure 2, Figure 5, Figure 6, and Figure 7]. There are well-defined radiographic criteria that are highly sensitive and specific for sigmoid volvulus.⁶ If there is any uncertainty regarding the presence, type, or level of colonic obstruction, immediate sigmoidoscopy followed by barium enema is diagnostic.

LABORATORY TESTS

Serum electrolyte concentrations, the hematocrit, the serum creatinine concentration, and the coagulation profile (prothrombin time [or international normalized ratio] and platelet count) are helpful in determining the severity of

Figure 3 Radiograph from a patient with postoperative ileus shows massive gastric distention (A), distended small bowel loops (B), air throughout the colon, mild dilatation of the sigmoid colon (C) with air mixed with stool, and a haustral fold in the apex of the sigmoid colon (D).

volume depletion and guiding resuscitative efforts. If ileus is suspected, serum magnesium and calcium levels should be measured, and urinalysis should be done to check for hematuria.

Determination of Need for Operation and Classification of Obstruction

The combination of a thorough history, a carefully performed physical examination, and correctly interpreted abdominal radiographs usually allows an experienced surgeon to identify the type of bowel obstruction present and to decide whether a patient requires immediate, urgent, or delayed operation [see Table 4] or can safely be treated initially with nonoperative measures. On the other hand, experienced surgeons may also have difficulty in properly identifying the cause and in deciding when to operate on a patient with intestinal obstruction. Given the importance of establishing a timely and accurate diagnosis on patient outcomes, it is strongly recommended that all patients suspected of having intestinal obstruction be admitted to a surgical hospital service; failure to do so can increase patient morbidity and mortality.⁷ To this end, it is particularly important and useful to stratify patients into those with mechanical obstruction and those with nonmechanical obstruction. In patients with mechanical bowel obstruction, an effort should be made to determine whether the obstruction is complete or partial. Except for a few clinical situations, patients with complete bowel obstruction require immediate operation; conversely, patients with partial bowel obstruction rarely do.

Figure 4 Upright radiograph from the same patient as the supine radiograph in Figure 1 shows multiple air-fluid levels of varying size arranged in inverted Us. In the right lower pelvis, a loop of small bowel is seen in exactly the same location as on the supine abdominal film (black arrow), a finding suggestive of adhesive obstruction.

Figure 5 (a) Radiograph from a patient with massive sigmoid volvulus shows a distended ahastral sigmoid loop (*white arrow*), inferior convergence of the walls of the sigmoid loop to the left of the midline, and approximation of the medial walls of the sigmoid loop as a summation line (*black arrow*). (b) Barium enema of the colon shows a tapered obstruction at the rectosigmoid junction with a typical bird's beak deformity (*black arrow*).

Figure 6 (a) Radiograph from a patient with cecal volvulus shows a dilated cecum with no air distally in the colorectum. Convergence of the medial walls of the loop (*black arrow*) points to the right, a typical finding in cecal volvulus. (b) Barium examination demonstrates a bird's beak deformity tapering at the point of volvulus (*large white arrow*). Note walls of dilated cecum (*small white arrows*).

Figure 7 Radiograph from a patient with complete colonic obstruction from an obstructing carcinoma in the descending left colon with proximal air-fluid levels. The absence of air distally in the rectum or the sigmoid is suggestive of complete obstruction. The ileocecal valve is competent; thus, there is no small bowel air.

Finally, an effort should be made to establish the level and cause of obstruction because these factors often help guide therapy and affect the probability of success in response to specific therapeutic intervention. Patients with nonmechanical obstruction, which derives from ileus or pseudo-obstruction [see Ileus and Pseudo-obstruction, below], do not require immediate operation.

Table 4 Guidelines for Operative and Nonoperative Therapy

Situations necessitating emergent operation
Incarcerated, strangulated hernias
Peritonitis
Pneumatosis cystoides intestinalis
Pneumoperitoneum
Suspected or proven intestinal strangulation
Closed-loop obstruction
Nonsigmoid colonic volvulus
Sigmoid volvulus associated with toxicity or peritoneal signs
Complete bowel obstruction
Situations necessitating urgent operation
Progressive bowel obstruction at any time after nonoperative measures are started
Failure to improve with conservative therapy within 24–48 hr
Early postoperative technical complications
Situations in which delayed operation is usually safe
Immediate postoperative obstruction
Sigmoid volvulus successfully decompressed by sigmoidoscopy
Acute exacerbation of Crohn disease, diverticulitis, or radiation enteritis
Chronic, recurrent partial obstruction
Paraduodenal hernia
Gastric outlet obstruction
Postoperative adhesions
Resolved partial colonic obstruction

ADJUNCTIVE TESTS FOR EQUIVOCAL SITUATIONS

Sigmoidoscopy

When one is uncertain whether or not the obstruction is mechanical on the basis of the information in hand, additional diagnostic measures are immediately indicated. When large amounts of colonic air extend down to the rectum, flexible or rigid sigmoidoscopy will readily exclude a rectal or distal sigmoid obstruction. Care must be exercised to avoid insufflating large amounts of air during endoscopy: excessive insufflation can cause overdistention of the colon above the level of the possible obstruction, which can be counterproductive and harmful. If sigmoidoscopy yields normal findings but partial colonic obstruction seems to be the correct diagnosis, a water-soluble contrast enema should be administered.⁸

Barium studies may be harmful in patients with acute obstruction when they are performed before the nature of the obstruction (complete or partial) is determined. Abdominal ultrasonography, although not as definitive as a contrast examination, is also able to diagnose suspected colonic obstruction in 85% of patients.⁹

Ultrasonography, Computed Tomography, and Fast Magnetic Resonance Imaging

Abdominal radiographs can be entirely normal in patients with complete, closed-loop, or strangulation obstruction.⁹ Therefore, if the patient's clinical profile and the results of physical examination are consistent with intestinal obstruction despite normal abdominal radiographs, abdominal ultrasonography, computed tomography (CT), or fast magnetic resonance imaging (MRI) should be performed immediately.^{10–19} All three modalities are highly sensitive and specific for intestinal obstruction when performed properly and interpreted by experienced clinicians. Two prospective clinical trials found ultrasonography to be as sensitive as and more specific than abdominal radiography in diagnosing intestinal obstruction.^{20,21} Ultrasonography, CT, and fast MRI are all capable of detecting the cause of the obstruction, as well as the presence of closed-loop or strangulation obstruction.^{9,11,16–19,22–25}

Sonographic criteria have been established for small bowel and colonic obstruction^{9,22,23}: (1) simultaneous observation of distended and collapsed bowel segments, (2) free peritoneal fluid, (3) inspissated intestinal contents, (4) paradoxical pendulating peristalsis, (5) highly reflective fluid within the bowel lumen, (6) bowel wall edema between serosa and mucosa, and (7) a fixed mass of aperistaltic, fluid-filled, dilated intestinal loops. One group of authors has recommended that when abdominal radiographs are inconclusive or normal in patients with suspected colonic obstruction, ultrasonography, rather than CT or barium enema, should be the next diagnostic step.⁹ Ultrasonography is well suited to critically ill patients: because it can be performed at the bedside, the risk associated with transport to the radiology suite is avoided. Given that ultrasonography is relatively inexpensive, is easy and quick to perform, and often can provide a great deal of information about the location, nature, and severity of the obstruction, it should be employed early in the evaluation of all patients with intestinal obstruction.²⁰

Several authors have recommended that patients with suspected small bowel obstruction and equivocal plain abdominal films undergo CT before a small bowel contrast series is

Figure 8 Computed tomography scan from a patient with partial small bowel obstruction shows distended, fluid-filled loops of small bowel with air-fluid levels, hyperemia, and bowel wall thickening (large white arrow). Note the discrepancy in caliber between dilated small bowel and decompressed small bowel (dashed white arrow) and the stranding (small black arrow) in the small bowel mesentery. Air in a decompressed descending colon (large black arrow) is indicative of partial obstruction.

ordered.^{12–15} CT has several advantages over a small bowel contrast examination in this setting: (1) it can ascertain the level of obstruction, (2) it can assess the severity of the obstruction and determine its cause, and (3) it can detect closed-loop obstruction and early strangulation [see Figure 8, Figure 9, Figure 10, and Figure 11]. CT can also detect

Figure 9 Computed tomography scan from a patient with adhesive partial small bowel obstruction shows a massively dilated small intestine (black arrow) proximal to a thick adhesive band (large white arrow) and decompressed small bowel distal to the adhesion (dashed white arrow). The patient was operated on because of the low probability that this obstruction would resolve with conservative management.

Figure 10 Computed tomography (CT) scan from a patient with partial small bowel obstruction from cancer shows a distended small bowel (dashed white arrows) proximal to a mass (small white arrow). There is air in the cecum (black arrow), the transverse colon, and the descending colon (large white arrow). The small bowel is maximally dilated, with a hyperemic, edematous bowel wall (B) just proximal to an obstructing recurrent colon carcinoma. Even though plain radiographs showed partial small bowel obstruction, this CT scan led to early operation because continued nonoperative management would not resolve the problem.

inflammatory or neoplastic processes both outside and inside the peritoneal cavity and can visualize small amounts of intra-peritoneal air or pneumatosis cystoides intestinalis not seen on conventional films [see Figure 10]. Prospective studies have demonstrated that the accuracy of CT in diagnosing bowel obstruction is higher than 95% and that its sensitivity and

Figure 11 Early closed-loop small bowel obstruction computed tomography (CT) scan from a patient with early closed-loop obstruction of the small intestine shows a markedly edematous, hyperemic small bowel, a finding indicative of early strangulation (white arrow). The patient had minimal symptoms, and there was air in the transverse colon and the descending colon (a finding indicative of partial small bowel obstruction); however, the finding of a gangrenous, nonperforated small bowel on this CT scan led to an early operation.

specificity are each higher than 94%.^{24,25} CT distinguishes colonic mechanical obstruction from pseudo-obstruction more accurately than conventional films do and thus is the preferred modality in many cases.²⁶

There is evidence to indicate that fast MRI with T₂-weighted (spin-spin relaxation time) images is more sensitive, specific, and accurate than contrast-enhanced helical CT in establishing the location and cause of bowel obstruction.¹⁸ The advantages of fast MRI over helical CT are (1) that the image acquisition time is short (1 to 2 seconds per slice), which means that the image can be acquired in the space of a single held breath; (2) no contrast agents are required; and (3) the avoidance of ionizing radiation. In addition, because of its multiplanar capability, MRI is also more effective at demonstrating the transition point of the obstruction and the ability to provide real-time and functional evaluation.²⁷ When helical CT is nondiagnostic in a patient with suspected bowel obstruction and fast MRI is not available, a small bowel follow-through examination with dilute barium is often useful.¹⁵

Contrast Studies

Enteroclysis (direct injection of BaSO₄ into the small bowel) is generally considered the most sensitive method of distinguishing between ileus and partial mechanical small bowel obstruction: it has a diagnostic sensitivity of 87% for adhesive obstruction.^{28,29} Many surgeons are concerned that injection of barium might cause partial obstruction to progress to complete obstruction; however, there is no evidence that this ever occurs, and one therefore should not refrain from using barium to diagnose partial small bowel obstruction.^{30–33} If complete obstruction is identified, the patient should undergo immediate operation. If partial obstruction is identified in either the small or the large bowel, the patient is treated accordingly. If (1) mechanical obstruction is not identified and (2) a point of obstruction, as evidenced by the finding of both dilated and decompressed intestinal loops, cannot be identified through abdominal ultrasonography, CT, or fast MRI, then the diagnosis is almost certainly ileus, in which case, one's attention is directed toward identifying and correcting the underlying precipitating cause [see Table 1 and Mechanical Obstruction, No Operation, and Adhesive Partial Small Bowel Obstruction, below].

Mechanical Obstruction

MALIGNANT BOWEL OBSTRUCTION

Malignant bowel obstruction (MBO) is a serious complication and most commonly affects patients with abdominal and pelvic tumors. Some patients will present with advanced disease for which curative surgical intervention is not feasible. For those patients, palliative efforts should focus on controlling gastrointestinal symptoms and restoring or preserving quality of life. Avoidance of operation in these patients is desirable. Etiologies for MBO include extrinsic occlusion of the lumen, malignant infiltration of mesentery and intestinal muscle and serosal surfaces, and intraluminal obstruction. Intestinal immobility secondary to opioids, certain antiemetics, and secondary adrenal insufficiency³⁴ may all play a role in MBO. Early and intensive pharmacologic treatment

with a combination of antisecretory drugs, analgesics, and antiemetics has been shown to be effective in controlling GI symptoms and even reverse functional MBO.³⁵ Three prospective, randomized clinical trials demonstrated that octreotide significantly attenuated the severity of nausea and vomiting and the degree of subjective discomfort in patients with inoperable obstruction and permitted the discontinuance of nasogastric tube decompression.^{36–38} One of these studies also demonstrated that octreotide significantly reduced the degree of fatigue and anorexia experienced.³⁸ One trial demonstrated the safety and efficacy of intramuscular long-acting octreotide once a month in patients with advanced cancer in relieving the symptoms of bowel obstruction.³⁹ Some patients with proximal or distal high-grade MBO may be successfully treated by endoscopic deployment of intraluminal stents and thus avoid laparotomy.^{40–42} This treatment option not only provides a better quality of life for patients with colorectal obstruction without the psychological repercussions of a colostomy but also appears to be cost-effective.⁴³ When long-term gastric decompression is required for palliation in a terminally ill patient with gastroduodenal obstruction, percutaneous endoscopic gastrostomy or jejunostomy should be considered [see 5:18 Gastrointestinal Endoscopy].⁴⁴ Patients who do not wish to die of MBO in a hospital should be offered hospice care or home visiting nurse services with continuous octreotide infusion, IV rehydration, and gastrostomy decompression.^{45,46} Attention must always be paid to quality-of-life issues and to the patient's potential interest in pursuing nonoperative forms of palliation. For many terminally ill or incurable patients with bowel obstruction, the most humane and sensible treatment comprises nothing more than instituting comfort measures, including continuous morphine infusion, rehydration, and administration of antisecretory agents.^{36,37,47}

IMMEDIATE OPERATION

All patients with complete bowel obstruction, whether of the small or large intestine, should undergo immediate operation unless extraordinary circumstances (e.g., diffuse carcinomatosis, terminal illness, or sigmoid volvulus that responds to sigmoidoscopic decompression) are present. If one attempts to manage complete intestinal obstruction nonoperatively, one risks delaying definitive treatment of patients with intestinal ischemia and subjecting them to significantly increased morbidity and mortality should perforation or severe infection develop.^{5,48}

Immediate operation is also indicated when bowel obstruction is associated with peritonitis; incarcerated strangulated hernias; suspected or confirmed strangulation; pneumatosis cystoides intestinalis; sigmoid volvulus accompanied by systemic toxicity or peritoneal irritation; colonic volvulus above the sigmoid colon; or fecal impaction. These conditions will not resolve without operation and are associated with increased morbidity, mortality, and cost if diagnosis and treatment are delayed. The only time one would not operate immediately on any patient with one of these diagnoses is when the patient requires cardiopulmonary stabilization,

additional resuscitation, or both. Whenever there is any doubt as to the presence of any of these conditions, additional diagnostic tests (e.g., ultrasonography, CT, fast MRI, or contrast studies) are indicated to confirm or exclude them.

Strangulation and Closed-Loop Obstruction

Morbidity and mortality from intestinal obstruction vary significantly and depend primarily on the presence of strangulation and subsequent infection. Strangulation obstruction occurs in approximately 10% of all patients with small intestinal obstruction. It carries a mortality of 10 to 37%, whereas simple obstruction carries a mortality of less than 5%.^{5,30,49,50} Early recognition and immediate operative treatment of strangulation obstruction are the only current means of decreasing this mortality. Strangulation obstruction occurs most frequently in patients with incarcerated hernias, closed-loop obstruction, volvulus, or complete bowel obstruction; hence, identification of any of these specific causes of obstruction is an important and clear indication for immediate operation. Radiographic evidence of pneumatosis cystoides intestinalis or free intraperitoneal air in a patient with a clinical picture of bowel obstruction is indicative of strangulation, perforation, or both and constitutes an indication for operation. High-quality abdominal CT with IV contrast can detect advanced strangulation and identify early, reversible strangulation [see Figure 11].^{14,16,17}

Abdominal ultrasonography can also identify edematous, hemorrhagic loops of intestine. Accordingly, whenever one is concerned about possible strangulation or closed-loop obstruction but is not yet committed to taking the patient immediately to the OR, an ultrasonogram or a CT scan should be obtained. In fact, given that ultrasonography, CT, and fast MRI are the only well-established means of diagnosing strangulation obstruction short of exploratory laparotomy or laparoscopy, an argument can be made that one of these modalities should be performed in all patients who have been admitted to the hospital with bowel obstruction and are initially being treated nonoperatively.

Many surgeons base the decision of whether to operate on patients with bowel obstruction on the presence or absence of the so-called classic signs of strangulation obstruction—continuous abdominal pain, fever, tachycardia, peritoneal signs, and leukocytosis—and on their clinical experience. Unfortunately, these classically taught signs, even in conjunction with abdominal x-rays and clinical judgment, are incapable of reliably detecting closed-loop or gangrenous bowel obstruction.^{5,30,48,51} In fact, one prospective clinical trial concluded that the five classic signs of strangulation obstruction and experienced clinical judgment were not sensitive for, specific for, or predictive of strangulation⁵: in more than 50% of the patients who had intestinal strangulation, the condition was not recognized preoperatively. Such findings suggest that early nonoperative recognition of intestinal strangulation is not feasible without ultrasonography, CT, or fast MRI. On the other hand, CT findings consistent with intestinal obstruction, when combined with the above clinical stigma (tenderness, tachycardia, fever, and leukocytosis), improve the diagnostic accuracy of CT scan to detect strangulated small bowel obstruction.⁵²

Incarcerated or Strangulated Hernias

A hernia that is incarcerated, tender, erythematous, warm, or edematous is an indication for immediate operation.

Primary or incisional hernias may not be palpable in obese patients, in which case, ultrasonography, CT [see Figure 12], or fast MRI should be performed.

Nonsigmoid Volvulus and Sigmoid Volvulus with Systemic Toxicity or Peritoneal Signs

All intestinal volvuli are closed-loop obstructions and thus carry a high risk of intestinal strangulation, infarction, and perforation. Patients typically present with acute, colicky abdominal pain, massive distention, nausea, and vomiting. Sigmoid volvulus is the most common form of colonic volvulus, followed by cecal volvulus. Abdominal radiographs are fairly diagnostic for colonic volvulus [see Figure 5 and Figure 6]. In contrast, small bowel volvulus may not be visualized on plain radiographs, because the closed loop fills completely with fluid and no air-fluid level can be seen. Small bowel volvulus is readily detected by ultrasonography or CT; one or both of these procedures should be performed in patients presenting with signs and symptoms of bowel obstruction and normal abdominal radiographs. Small bowel volvulus is an indication for immediate operation.

If one observes signs of systemic toxicity, a bloody rectal discharge, fever, leukocytosis, or peritoneal irritation in a patient with sigmoid volvulus, the patient should undergo immediate operation; if all of these signs are absent, the patient should undergo sigmoidoscopy. When there are no signs of peritonitis or generalized toxicity, sigmoidoscopic decompression is safe and effective in more than 95% of patients with sigmoid volvulus.⁵³ If mucosal gangrene or a bloody effluent is noted at the time of sigmoidoscopy, immediate operative intervention is necessary even in the absence of any clinical signs or symptoms of strangulation. After sigmoidoscopy, the patient can undergo elective bowel preparation and a single-stage sigmoid resection before being discharged from the hospital. If, however, clinical toxicity, a bloody rectal discharge, fever, or peritoneal irritation arises at any time after sigmoidoscopic decompression while the patient is being prepared for an elective procedure, immediate operation is indicated.

Patients with volvulus proximal to the sigmoid colon should undergo immediate operation regardless of whether peritoneal irritation is present. The incidence of strangulation infarction is high in such patients, and nonoperative therapy often fails. If the diagnosis of nonsigmoid colonic volvulus is in doubt, a barium enema is indicated to exclude colonic pseudo-obstruction.

Fecal Impaction

Complete colonic obstruction secondary to fecal impaction in the rectum can sometimes be successfully relieved through disimpaction at the bedside; however, this can be difficult and extremely uncomfortable for the patient. The most expeditious and successful method of relieving the obstruction is to disimpact the patient while he or she is under general or spinal anesthesia. In one study, the pulsed-irrigated enhanced-evacuation procedure, which can be performed at the bedside, successfully resolved fecal impaction in approximately 75% of geriatric patients.⁵⁴ In another study, administration of a polyethylene glycol 3350 solution over 3 days successfully resolved intestinal obstruction from fecal impaction in 75% of pediatric patients.⁵⁵

Figure 12 Sagittal (a) and coronal (b) views demonstrate an incarcerated/strangulated bowel in the right inguinal hernia.

URGENT OPERATION

Lack of Response to Nonoperative Therapy within 24 to 48 Hours

It is usually safe to manage partial bowel obstruction initially by nonoperative means: a nil per os (NPO) regimen, nasogastric decompression, analgesics, and octreotide. Such therapy is successful in most cases, especially if the cause of obstruction is postoperative adhesions, but there is always the risk that complete bowel obstruction or strangulation already exists but is undetected. Furthermore, there is the risk that while the patient is being observed, partial obstruction will progress to complete obstruction, or strangulation and perforation will develop. It is therefore crucial to be alert to changes in the patient's condition.

Repeated examination of the abdomen by the same clinician is the most sensitive way of detecting progressive obstruction. Examinations should be performed no less frequently than every 3 hours. If abdominal pain, tenderness, or distention increases or the gastric aspirate changes from nonfeculent to feculent, abdominal exploration is usually indicated. Abdominal radiographs should be repeated every 6 hours after nasogastric decompression and reviewed by the surgeon who is following the patient. If proximal small bowel distention increases or distal intestinal gas decreases, nonoperative therapy is less likely to be successful; in these circumstances, early operative intervention should be seriously considered. Conversely, if the patient's condition appears stable or improved and x-rays indicate that the obstruction either has resolved somewhat or at least is no worse, it is generally safe to continue nonoperative care for another 12 to 24 hours. If the clinical picture is stable after 24 hours of observation, one must decide whether to operate or to continue nonoperative therapy. Clinical judgment and experience, coupled with a thorough and accurate assessment of the patient's underlying

diagnosis and clinical condition, have traditionally been the most reliable guides for making this decision. Currently, however, it appears that the decision whether to operate can be made more cost-effectively and reliably on the basis of abdominal imaging studies [see No Operation and Adhesive Partial Small Bowel Obstruction, below].

Early Postoperative Technical Complications

When normal bowel function initially returns after an abdominal operation but then is replaced by a clinical picture suggestive of early postoperative mechanical obstruction, the explanation may be a technical complication of the operation (e.g., phlegmon, abscess, intussusception, a narrow anastomosis, an internal hernia, or obstruction at the level of a stoma). An early, aggressive diagnostic workup should be performed to identify or exclude these problems because they are unlikely to respond to nasogastric decompression or other forms of conservative management. It is critical to know exactly what was done within the abdomen in the course of the operation. To this end, one should try to speak directly with the operating surgeon rather than attempt to deduce the needed information from the operative report.

If the patient had peritonitis or a colonic anastomosis at the initial operation, one should order a CT scan to look for an intra-abdominal abscess. An abscess or a phlegmon at the site of an anastomosis is usually secondary to anastomotic leakage and is an indication for reoperation. CT can also identify intra-abdominal hematomas, which should be evacuated through early reoperation. In patients recovering from a proctectomy, herniation of the small bowel through a defect in the pelvic floor is a common cause of intestinal obstruction. Oral contrast studies can help identify patients with an internal hernia, intussusception, or anastomotic obstruction and should be performed after the CT scan. A retrograde barium examination should be performed in patients thought to have a problem related to a stoma or an intestinal anastomosis. When none of the above factors appear to be the cause of the postoperative obstruction, it is reasonable for the surgeon to assume that the obstruction is secondary to postoperative adhesions, which are best treated conservatively (see below).

NO OPERATION

In selected patients, non-operative management of partial small bowel obstruction is highly successful and carries an acceptably low mortality. Such patients include those whose partial obstruction is secondary to intra-abdominal adhesions, occurs in the immediate postoperative period, or derives from an inflammatory condition (e.g., inflammatory bowel disease, radiation enteritis, or diverticulitis).

Adhesive Partial Small Bowel Obstruction

Adhesions are the major cause of bowel obstruction. Obstruction resulting from adhesions can occur as early as 1 month or as late as 20 years after operation.⁵⁶ Adhesive partial small bowel obstruction is treated initially with nasogastric decompression, IV rehydration, and analgesia. Parenteral nutrition should be begun if one believes that oral or enteral nutrition will not be adequate within 5 days. Non-operative therapy leads to resolution of adhesive partial obstruction in as many as 90% of patients^{57,58}; however, such resolution is followed by recurrence of obstruction in approximately 50% of cases.^{59,60} When operative adhesiolysis is performed, the mortality is less than 5% for patients with simple obstruction but may be as high as 30% for patients with strangulation or a necrotic bowel necessitating intestinal resection.⁵⁶ In view of this substantial difference in mortality, it is extremely important to be able to confidently distinguish obstruction that is likely to resolve with nonoperative treatment from obstruction that is not. Patients with adhesive partial obstruction that can be accurately predicted to resolve with medical therapy can and should be treated nonoperatively.

Some studies suggest that the nature of the previous abdominal operation or the type of adhesions present may influence the probability that the obstruction will not respond to medical therapy.^{61–65} Operations associated with a lower likelihood of response to medical therapy include those performed through a midline incision; those involving the aorta, colon, rectum, appendix, or pelvic adnexa; and those done to relieve previous carcinomatous obstruction. Matted adhesions, which are more common in patients who have undergone midline incisions or colorectal procedures, are less amenable to conservative management than a simple obstructive band is.⁶¹ In the context of this kind of operative history, strong consideration should be given to surgical intervention if the obstruction does not resolve within 24 hours—unless comorbid medical conditions tip the risk-benefit balance in the direction of nonoperative therapy.

There is an ongoing debate regarding how long patients with partial adhesive obstruction should be treated conservatively. After 48 hours of nonoperative management, the risk of complications increases substantially, and the probability that the obstruction will resolve diminishes.⁵⁰ Generally, if the obstruction is going to resolve with nonoperative therapy, there will be a fairly prompt response within the first 8 to 12 hours. Therefore, if a patient's condition has deteriorated or has not significantly improved by 12 hours after nasogastric decompression and resuscitation, exploratory laparotomy

is advisable. During this observation period, the patient must be constantly reevaluated, ideally by the same examiner. Analgesics can be safely administered, and repeat abdominal examinations should be performed at 3-hour intervals when the influence of narcotics has waned. Repeat abdominal x-rays should be obtained no later than 6 hours after nasogastric decompression, and the pattern of gas distribution should be compared with that seen on the admission films. A decrease in intestinal gas distal to a point of obstruction coupled with an increase in proximal dilatation suggests that the obstruction is worsening; conversely, a decrease in intestinal distention coupled with the appearance of more gas distally in the colon suggests that the obstruction is being reduced. The degree of abdominal distention, the passage of flatus, and the nature of the nasogastric aspirate should be evaluated periodically. If abdominal distention does not decrease or the gastric aspirate changes from bilious to feculent, the patient should be operated on.

Experimental and clinical studies suggest that patients undergoing nonoperative treatment of bowel obstruction may benefit from the administration of somatostatin analogues as a result of the potent effects these substances exert on intestinal sodium, chloride, and water absorption.⁶⁵ In one study, animals with either complete or closed-loop partial small bowel obstruction were given either long-acting somatostatin or saline; the treatment group had significantly less intestinal distention, less infarction, and longer survival than the control group.^{65,66} In a prospective, randomized clinical trial evaluating the use of somatostatin in patients who had complete small bowel obstruction without clinical or radiologic evidence of strangulation, the treatment group was less likely to need operation, had less proximal intestinal distention, and exhibited decreased mucosal necrosis proximal to the point of obstruction.⁶⁷ In other trials, long-acting somatostatin analogues and other nonsecretagogues significantly decreased the amount of gastric contents aspirated and alleviated the symptoms of intestinal obstruction in terminally ill patients with nonoperable malignant disease.^{36,38–47}

It should be possible to determine with a high degree of accuracy and safety which patients will require an operation for adhesive small bowel obstruction within 24 to 48 hours of admission to the hospital. As a rule, patients with closed-loop or complete bowel obstruction, who require an immediate or urgent operation, can be readily identified by means of abdominal CT or MRI.^{13–15,18,19} For the remaining patients, who have some degree of partial obstruction, the success or failure of conservative management can be predicted with high accuracy by recording the arrival of contrast material (either a water-soluble agent or a mixed barium preparation) in the right colon within a defined time.^{15,32} One prospective study documented the arrival of diatrizoate meglumine–diatrizoate sodium in the colon within 24 hours and found this measure to have a sensitivity of 98%, a specificity of 100%, an accuracy of 99%, a positive predictive value of 100%, and a negative predictive value of 96% as a predictor of successful nonoperative treatment.⁶⁸ Other studies achieved comparable results with shorter arrival times (e.g., 4 or 8 hours).^{15,69,70}

Several prospective, randomized clinical trials have addressed the issue of whether administration of contrast

material can itself be therapeutic with respect to resolving adhesive small bowel obstruction. Two such studies examined small bowel follow-through with barium, either alone or mixed with diatrizoate meglumine.^{32,33} Both found that the intervals between admission and operation were shorter for patients randomized to the contrast arm than for those in the control group but that contrast examination did not lead to more expeditious resolution of obstruction. Both studies also demonstrated that barium could be administered to patients with small bowel obstruction safely and without complications.

Meta-analysis investigating the effect of administering water-soluble hyperosmolar contrast agents to patients with small bowel obstruction revealed that the appearance of water-soluble contrast agent in the colon on an abdominal radiograph within 24 hours of its oral administration predicts the resolution of obstruction with a sensitivity of 97% and a specificity of 96%. Although a Gastrografin dose not reduce the need for an operation, it appears to shorten the hospital stay for those who do not require surgery [see Figure 13].⁷¹

By accelerating the resolution of partial small bowel obstruction and ileus, administration of water-soluble contrast agents can shorten the expected hospital stay and thereby reduce the cost of care. Thus, it is reasonable that the first step in managing suspected partial small bowel obstruction from adhesions or postoperative ileus should be to administer water-soluble contrast material intragastrically. When bowel function does not return within 24 hours and the obstruction is demonstrated to be partial, continued observation is safe and resolution without operation is still highly probable.

Figure 13 The presence of contrast in the colon after 4 hours of its administration predicts resolution of small bowel obstruction with a sensitivity of 97% and a specificity of 96%.

Eventually, however, there will be a point beyond which continued observation is no longer cost-effective in comparison with operative adhesiolysis (especially laparoscopic adhesiolysis). Additional prospective trials are necessary to determine precisely how long the waiting period before operative treatment should be.

Laparoscopic adhesiolysis Several clinical reports have demonstrated that laparoscopic adhesiolysis for acute small bowel obstruction is both feasible and safe.^{72–77} Laparoscopic or laparoscopic-assisted lysis of adhesions relieves bowel obstruction in more than 50% of patients and is associated with lower morbidity, earlier return of bowel function, quicker resumption of a normal diet, and a shorter hospital stay than open operative lysis.^{68–76,78} To minimize the risk of bowel injury at the beginning of the operation, the first trocar is inserted under direct vision by means of an open technique, and the incision is placed well away from any previous scars.^{79,80}

At present, there are no prospective, randomized, controlled clinical trials comparing laparoscopic with open adhesiolysis. In a retrospective, matched-pair analysis that used an intention-to-treat analysis, 52% of the patients in the laparoscopic group underwent conversion to open lysis of adhesions either for completion of adhesiolysis or for management of complications.⁷⁶ No perforations or recurrent obstructions were missed. Perforations were more common overall in the laparoscopic group than in the open group, although this difference was largely eliminated when patients from the laparoscopic group who underwent conversion to open lysis were not considered. Patients with two or more previous laparotomies had a higher incidence of intraoperative complications than those with fewer laparotomies. Accordingly, the authors recommended against laparoscopic adhesiolysis in patients with two or more previous laparotomies. The high conversion rate in this study notwithstanding, the laparoscopic group as a whole (including conversions) experienced an overall reduction in postoperative complications.

Another potential advantage of laparoscopic adhesiolysis is that it results in fewer intra-abdominal adhesions than open laparotomy^{81,82} and thus may reduce the risk of recurrent bowel obstruction. However, one study found that despite a reduction in the median length of stay, patients treated laparoscopically were at increased risk for an early unplanned reoperation as a consequence of either incomplete relief of obstruction or complications.⁷⁵ In fact, bowel perforation in the course of laparoscopic adhesiolysis often is not detected during the procedure and presents in a delayed fashion.⁸⁰ Many such injuries are attributable either to insertion of the initial trocar or to delayed perforation of a thermal injury. When laparoscopic adhesiolysis fails to identify and relieve an obvious point of obstruction or when adhesiolysis is inadequate or unsafe, conversion to an open approach is indicated. At present, the laparoscopic approach appears best suited to those patients who have undergone less than three previous operations or who have been seen early after the onset of obstruction, especially if they have undergone appendectomy only, as well as those in whom the probable cause of obstruction is from adhesive bands.⁸³

Early Postoperative Obstruction

Early postoperative mechanical small bowel obstruction is not uncommon: it occurs in approximately 10% of patients undergoing abdominal procedures.⁸⁴ Postoperative bowel obstruction is often difficult to diagnose because it gives rise to many of the same signs and symptoms as postoperative ileus: obstipation, distention, nausea, vomiting, abdominal pain, and altered bowel sounds. In most cases, there are roentgenographic signs indicative of small bowel obstruction rather than ileus; however, in some cases, abdominal x-rays fail to diagnose the obstruction.⁸⁵ Traditionally, when plain radiographs are equivocal, an upper GI barium study with follow-through views is the next test performed to distinguish ileus from partial or complete small bowel obstruction⁸⁶; however, such studies may yield the wrong diagnosis in as many as 30% of cases.^{27,85,87} A number of authorities believe that abdominal ultrasonography is excellent at distinguishing postoperative ileus from mechanical obstruction and recommend that it be done before any contrast study.²³

Early postoperative obstruction is caused by adhesions in about 90% of patients.^{85,88} When there are no signs of toxicity and no acute abdominal signs, such obstruction can usually be managed safely with nasogastric decompression.^{84,85,87,88} As many as 87% of patients respond to nasogastric suction within 2 weeks. About 70% of the patients who respond to nonoperative treatment do so within 1 week, and an additional 25% respond during the following 7 days. If postoperative obstruction does not resolve in the first 2 weeks, it is unlikely to do so with continued nonoperative therapy, and reoperation is probably indicated^{85,88}; about 25% of patients whose postoperative obstruction was initially treated nonoperatively eventually require reoperation. An exception to this guideline arises in patients known to have severe dense adhesions (sometimes referred to as obliterative peritonitis) in response to multiple sequential laparotomies. These patients may have a combination of mechanical obstruction and diffuse small bowel and colonic ileus. The risk of closed-loop obstruction, volvulus, or strangulation in this group of patients is low. Repeat laparotomies and attempts to lyse adhesions may lead to complications, the development of enterocutaneous fistulae, or exacerbation of the adhesions. Often the best approach to managing these patients is observation for prolonged periods (i.e., months). Total parenteral nutrition (TPN) is indicated. The addition of octreotide to the TPN solution may be helpful and may make patients more comfortable.

Because the risk of intestinal strangulation in patients with postoperative adhesive obstruction is extremely low (< 1%),^{85,89} one can generally treat these patients nonoperatively for longer periods. In fact, the conservative approach is often the wise one: reoperation may do more harm than good (e.g., by causing enterotomies and inducing denser adhesions). The traditional indications for operation in patients with early postoperative obstruction include (1) deteriorating clinical status, (2) worsening obstructive symptoms, and (3) failure to respond to nonoperative management within 2 weeks. With the rising cost of hospitalization, it might, in fact, be more cost-effective to reoperate on patients who have persistent obstruction after 7 days. This speculation would have to be tested by a well-organized cost-benefit study conducted in a prospective fashion.

Some physicians have maintained that long intestinal tubes are beneficial in the management of postoperative bowel obstruction.⁵⁸ However, there is no convincing evidence that long intestinal tubes are any better for resolving bowel obstruction than conventional nasogastric tubes are. In fact, some authorities have reported that the use of such tubes increases morbidity.^{30,50,51} One prospective, randomized clinical trial that addressed this issue found no differences between the two types of tube with respect to the percentage of patients who were able to avoid operation, the incidence of complications, the time between admission and operation, or the duration of postoperative ileus.⁹⁰

Inflammatory Conditions

Partial bowel obstruction secondary to inflammatory bowel disease, radiation enteritis, or diverticulitis usually resolves with nonoperative therapy. Bowel obstruction accompanying an acute exacerbation of Crohn disease usually resolves with nasogastric suction, IV antibiotics, and antiinflammatory agents. If, however, CT detects an intra-abdominal abscess, there is evidence of a chronic stricture, or the patient exhibits persistent obstructive symptoms, an operation may be necessary. Similarly, bowel obstruction arising from acute enteritis caused by radiation exposure or chemotherapy usually resolves with supportive care. Chronic radiation-induced strictures are problematic; astute clinical judgment must be exercised to determine when operative treatment is the best option.

Patients with acute diverticulitis typically present with a history of altered bowel movements, fever, leukocytosis, localized pain, tenderness, and guarding in the left lower quadrant of the abdomen. Approximately 20% of patients with colonic diverticulitis also present with signs and symptoms of partial colonic obstruction. A CT scan should be obtained early in all patients with diverticulitis to ascertain whether there is a pericolic abscess that could be drained percutaneously.⁹¹ Partial colonic obstruction in these patients usually resolves with antibiotic therapy, an NPO regimen, and nasogastric decompression. If obstructive symptoms persist for more than 7 days or if obstructive symptoms from a documented stricture recur, operation is indicated.

ELECTIVE OPERATION

Nontoxic, Nontender Sigmoid Volvulus

Patients with nontoxic, nontender sigmoid volvulus whose bowel obstruction is initially treated successfully with sigmoidoscopic decompression are at risk for recurrent colonic obstruction. Accordingly, these patients should undergo elective sigmoid resection after complete bowel preparation.

Recurrent Adhesive or Stricture-Related Partial Small Bowel Obstruction

Many patients whose adhesive bowel obstruction resolves experience no further obstructive episodes. If a patient does present with recurrent obstruction from presumed adhesions, either a contrast examination of the bowel or CT is indicated

to determine whether there is a surgically correctable point of stenosis. A strong argument can be made that non-high-risk patients should undergo elective operation after presenting with their second episode of mechanical obstruction. Similarly, patients with recurrent obstruction from strictures of any sort should undergo elective operation given that these lesions are unlikely to resolve.

Partial Colonic Obstruction

The most common causes of partial colonic obstruction are colon cancer, strictures, and diverticulitis. Cancer and strictures usually must be managed surgically because they generally go on to cause obstruction later. Strictures from ischemia or endometriosis usually call for elective colonic resection. Inflammatory strictures from diverticulitis may resolve; however, if obstructive symptoms persist or if barium enema examination continues to yield evidence of colonic narrowing, elective resection is warranted.

When abdominal x-rays suggest distal colonic obstruction, digital examination and rigid sigmoidoscopy are performed to exclude fecal impaction, tumors, strictures, and sigmoid volvulus. If obstruction is proximal to the sigmoidoscope, barium contrast examination is indicated. If barium examination does not demonstrate mechanical obstruction, a presumptive diagnosis of colonic pseudo-obstruction is made.

The morbidity and mortality associated with elective colectomy procedures are significantly lower than those associated with emergency colonic surgery. Furthermore, immediate operation for left-side colonic obstruction almost always necessitates the creation of a diverting colostomy. If a colostomy takedown subsequently proves necessary, the overall cost of caring for the patient will be significantly higher than it would have been had a single-stage procedure been performed. For these reasons, one should initially treat partial colonic obstruction with nasogastric suction, enemas, and IV rehydration in the hope that the obstruction will resolve and that the patient thus can undergo mechanical and antibiotic bowel preparation and a single-stage procedure comprising resection and primary anastomosis. Patients who do not respond to nonoperative measures within 24 hours should undergo operation within 12 hours with the aim of preventing perforation.

In patients with partially obstructing rectal or distal sigmoid tumors or strictures that can be traversed with a radiologic guide wire, balloon dilatation can be performed and a self-expanding stent deployed.^{92–95} Clinical improvement and resolution of obstruction occur in more than 90% of patients within 96 hours.⁹⁴ With restoration of the bowel lumen, patients can be prepared for elective surgery, can be spared the creation of a diverting colostomy, and can avoid the extra expense and morbidity associated with the performance of two operations.^{94,95} In a recent prospective trial, the management of acute colonic obstruction using endoscopic stent decompression prepared patients for laparoscopic resection and primary anastomosis with good results.⁹⁶

Bowel Obstruction without Previous Abdominal Operation

When partial small bowel obstruction develops and resolves in a patient who has not previously undergone an abdominal operation, a diagnostic workup should be performed to identify the cause of the obstruction; there may be an underlying condition that is likely to cause recurrent obstruction (e.g., an

internal hernia, a tumor, malrotation, or metastatic cancer). The first diagnostic test to be ordered should be a CT scan, followed by an upper GI barium study with follow-through views and a barium enema.⁹⁷ If a pathologic lesion is identified, elective operation is indicated. An argument can be made that no additional diagnostic tests should be performed in these patients and that diagnostic laparoscopy should be performed instead to enable laparoscopic surgery in case a cause of obstruction is identified that can be treated with a minimally invasive procedure. If no cause of obstruction is found at laparoscopy, open laparotomy is performed.

Paraduodenal hernia, a congenital defect resulting from intestinal malrotation, is probably more common than was once thought. It accounts for approximately 50% of internal hernias. Patients with paraduodenal hernia may present with a catastrophic closed-loop obstruction; more often, however, they exhibit mild, nonspecific GI symptoms such as nausea, vomiting, esophageal reflux, and abdominal pain. Duodenogastric reflux and prominent bile gastritis in the absence of a previous operation or diabetic gastroparesis are indirect signs of a paraduodenal hernia. The diagnosis is established by means of either an upper GI contrast study with small bowel follow-through or CT scanning. When a paraduodenal hernia is identified, operative treatment is indicated. Such treatment is usually successful in alleviating symptoms and preventing strangulation obstruction.⁹⁸

Nonmechanical Obstruction

ILEUS

Ileus, or intestinal paralysis, is most common after abdominal operations but can also occur in response to any acute medical condition or metabolic derangement [see Table 1]. The pathophysiologic mechanisms that cause ileus are incompletely understood but appear to involve disruption of normal neurohumoral responses.⁹⁹ Ileus may be classified into two broad categories: postoperative ileus and ileus without antecedent abdominal operation. Postoperative ileus is manifested by atony of the stomach, small intestine, and colon and usually resolves spontaneously within a few days as normal bowel motility returns. Typically, the small bowel regains its motility within 24 hours of operation, followed 3 to 4 days later by the stomach and colon. Initial therapy of ileus is directed at identifying and correcting the presumed cause [see Figure 14]. If the patient experiences abdominal distention, abdominal pain, nausea, or vomiting, then nasogastric decompression, placement of a Foley catheter, and IV rehydration are indicated. In postoperative patients, it is best not to use strong narcotics for analgesia and instead to rely on epidural anesthesia and nonsteroidal anti-inflammatory drugs. When ileus develops in patients who have not recently undergone an operation, a thorough history, a careful physical examination, and well-chosen laboratory tests are necessary to identify the possible causes.

When ileus persists for what is, in one's best clinical judgment, an inordinate length of time for the operation performed (typically, longer than 3 to 4 days), the possibility of partial mechanical obstruction, possibly associated with an

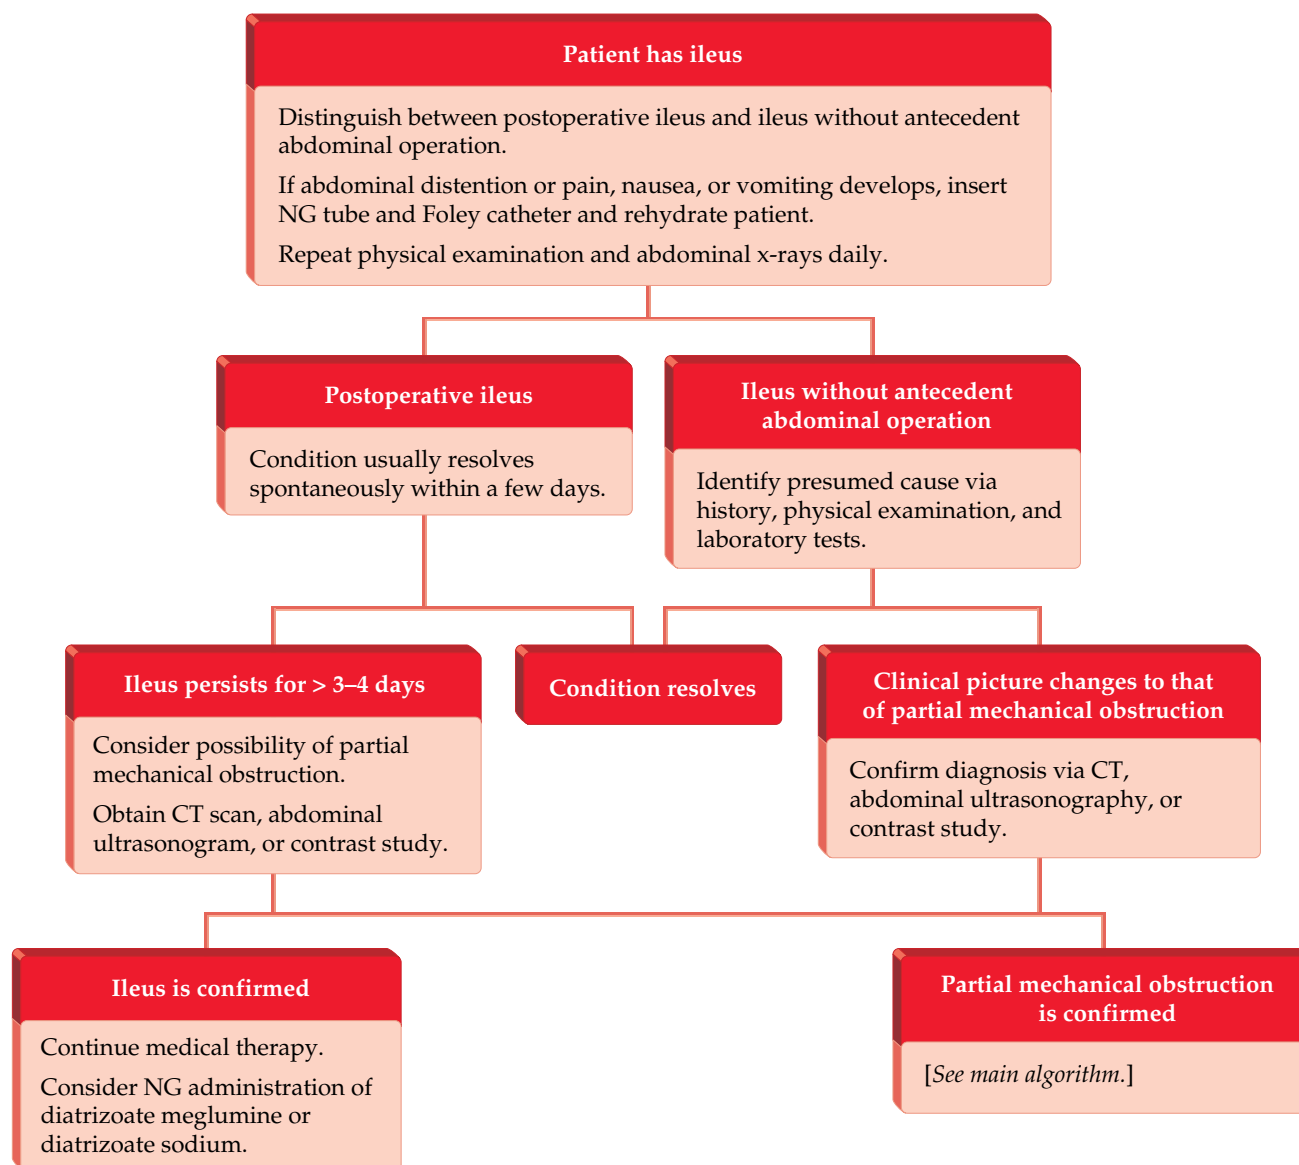

Figure 14 An algorithm outlining an approach to management of ileus. CT = computed tomography; NG = nasogastric.

intra-abdominal abscess or another source of infection, must be considered. If an abscess is suspected, an abdominal CT scan should be obtained. Abdominal ultrasonography has been reported to distinguish postoperative ileus from mechanical obstruction reliably.²³ A small bowel contrast examination with barium identifies partial mechanical small bowel obstruction in about 75% of patients.^{27,30} CT distinguishes ileus from obstruction in about 80% of patients.

Intragastric administration of a water-soluble contrast agent has shown great potential in the treatment of ileus.^{100,101} In one study, administration of 120 mL of diatrizoate meglumine or diatrizoate sodium via a nasogastric tube to 40 adults with postoperative small bowel ileus led to restored intestinal motility within 6 hours in all 40, allowing them to resume oral alimentation within 24 hours.¹⁰⁰ Given these results, a prospective, randomized trial that addresses cost-management end points is warranted.

PSEUDO-OBSTRUCTION

Pseudo-obstruction [see Figure 15] can exist in the small bowel or colon and can be either acute or chronic. Acute colonic pseudo-obstruction, also known as Ogilvie syndrome, is the most common form. Colonic pseudo-obstruction occurs most commonly in hospitalized patients in the postoperative period or in response to a nonsurgical acute illness (e.g., pneumonia, myocardial infarction, hypoxia, shock, intestinal ischemia, or electrolyte imbalance). The pathophysiologic mechanisms underlying idiopathic pseudo-obstruction appear to be related to an imbalance in the parasympathetic and sympathetic influences on colonic motility.

The presenting symptoms of acute colonic pseudo-obstruction are massive dilatation of the colon (with the cecum more dilated than the distal colon), crampy pain, nausea, and vomiting.¹⁰² If peritoneal irritation or systemic toxicity is present, immediate laparotomy is indicated; if not,

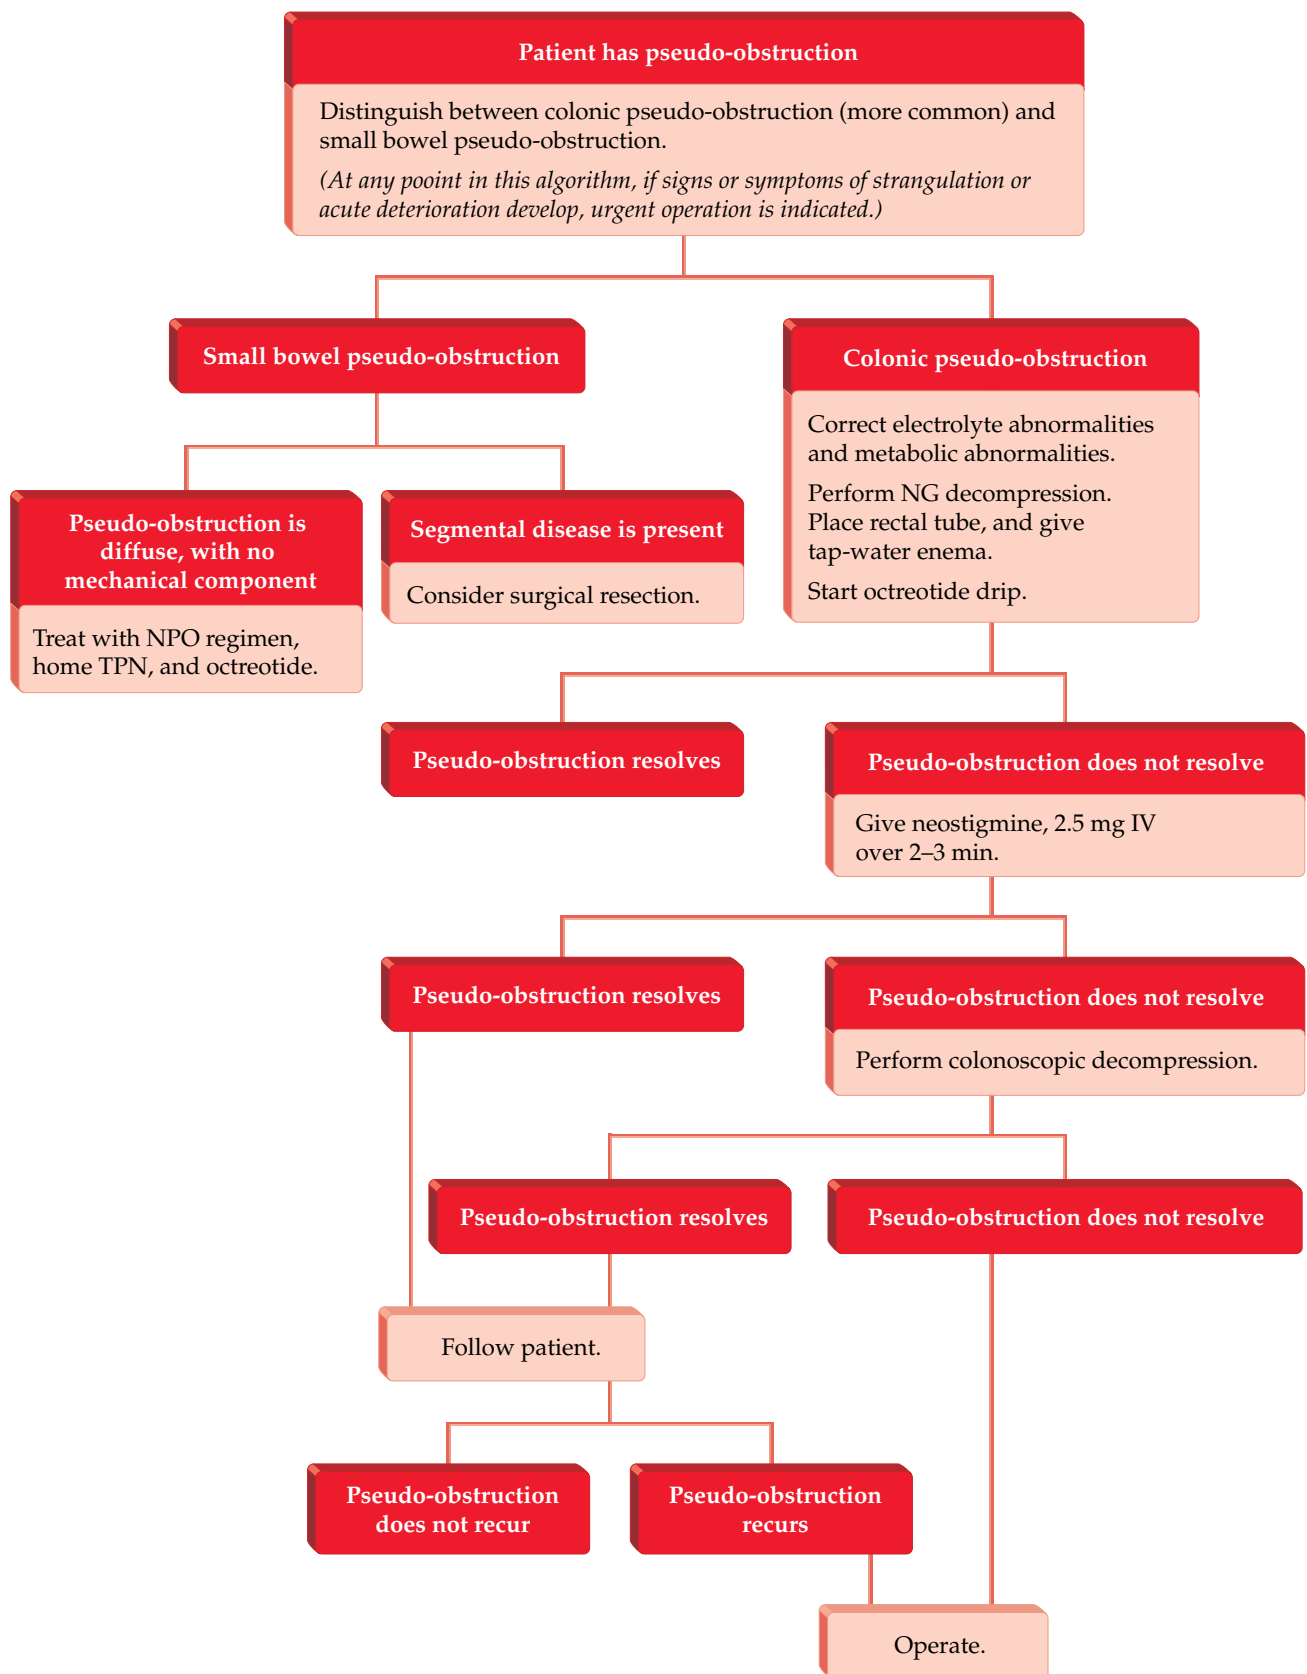

Figure 15 An algorithm outlining an approach to management of pseudo-obstruction. IV = intravenous; NG = nasogastric; NPO = nothing by mouth; TPN = total parenteral nutrition.

treatment involves nasogastric decompression, placement of a rectal tube, tap-water enemas, correction of any underlying metabolic disturbances, and avoidance of narcotic and anticholinergic medications. With conservative management, acute colonic pseudo-obstruction resolves within 4 days in more than 80% of cases.¹⁰³ Colonoscopy was previously the method of choice for decompression in this setting.¹⁰⁴ It has been shown, however, that IV administration of neostigmine, 2.5 mg over 2 to 3 minutes, leads to prompt resolution of acute colonic pseudo-obstruction within minutes in nearly all cases.^{105,106} Now that this previously difficult and potentially lethal problem can readily be treated pharmacologically, colonoscopic decompression and surgical intervention should be reserved for cases in which pharmacologic measures fail.

Chronic intestinal pseudo-obstruction is a rare acquired disorder that is caused by various diseases involving GI smooth muscle, the enteric nervous system, or the extrinsic autonomic nerve supply to the gut.¹⁰⁷ These disorders are treated with an NPO regimen, home TPN, and octreotide. Patients with chronic intestinal pseudo-obstruction should be followed closely for long periods and should undergo repeat contrast studies: a condition occasionally develops that can cause mechanical obstruction and that may be surgically correctable.^{108,109}

Cost Considerations

Cost considerations are exerting an ever-growing influence on surgical care in general and on the decision whether to operate in particular. A large percentage of the high total cost of caring for patients with ileus or mechanical intestinal obstruction is accounted for by the cost associated with hospitalization or the need for laparotomy. Bed stay for these admissions represents the equivalent of almost one surgical bed per year and at least 2 days of OR time.¹¹⁰

Strategies for reducing the overall cost of managing patients with bowel obstruction may take several forms: the development of diagnostic and therapeutic methods that lead to more rapid diagnosis and resolution of ileus and partial small bowel obstruction; the development of techniques for rapid identification of patients with complete or closed-loop obstruction and early reversible strangulation, which would permit earlier operative intervention and thereby reduce the incidence of

complications; the development of therapeutic approaches that prevent postoperative ileus, including the use of selective postoperative inhibition of gastrointestinal opioid receptors,¹¹¹ the use of a well-defined postoperative care program including continuous thoracic epidural analgesia and enforced early mobilization and enteral nutrition,¹¹² gum chewing,¹¹³ and avoiding positive salt and water balance¹¹⁴; and the development of methods for preventing intra-abdominal adhesions, which would significantly reduce the overall incidence of bowel obstruction. Two prospective, randomized clinical trials demonstrated that placement of a bioresorbable membrane composed of sodium hyaluronate and carboxymethylcellulose underneath abdominal fascial closures significantly reduced the severity and density of postoperative adhesions,^{115,116} and in one randomized controlled trial, the use of 4% icodextrin lavage plus instillation was well tolerated and reduced adhesion formation and reformation following laparoscopic gynecologic surgery.¹¹⁷ In theory, use of such a product should reduce the incidence of adhesion-related bowel obstruction; however, longer-term studies are required to determine whether this will actually be the case.

From a management viewpoint, if a specific diagnostic test, medication, or approach (e.g., laparoscopy) costs less than a day of hospitalization does, it immediately becomes cost-effective if it reduces complications and shortens length of stay by 1 day. Intra gastric administration of a water-soluble contrast agent to relieve small bowel ileus or partial adhesive obstruction is an example of an innovative, cost-effective therapeutic strategy. Diagnostic laparoscopy, abdominal ultrasonography, CT, and fast MRI have all been successfully used to make earlier definitive management decisions and to prevent gangrenous obstruction. Laparoscopic adhesiolysis also leads to earlier hospital discharge. On the basis of the collective experience reported in a substantial number of studies (see above), a logical proposal for cost-effective management of patients with bowel obstruction would be to perform ultrasonography or abdominal CT immediately after initial resuscitation and then to perform laparoscopic surgery on those patients in whom the contrast agent does not arrive in the right colon within 24 hours. However, prospective, randomized clinical trials are needed to evaluate the cost-effectiveness of this and other newer management strategies.

5 GASTROINTESTINAL BLEEDING

Eric S. Hungness, MD, FACS

Despite recent advances in therapeutic endoscopy and the widespread use of anti-secretory medications, upper gastrointestinal bleeding (UGIB)—defined as bleeding that occurs proximal to the ligament of Treitz—continues to be one of the more common reasons for surgical consultation. It also remains a significant source of mortality for both emergency admissions (11%) and inpatients (33%).¹ The most common causes of UGIB are esophageal (varices and Mallory-Weiss tears), gastric (acute hemorrhagic gastritis, varices, ulcers, and neoplasms), and duodenal (ulcers) [see Discussion and Management of Specific Sources of UGIB, below]. Less common causes include various other gastrointestinal (GI) conditions and certain hepatobiliary and pancreatic disorders.

Lower gastrointestinal bleeding (LGIB)—defined as abnormal hemorrhage into the lumen of the bowel from a source distal to the ligament of Treitz—usually derives from the colon; however, the small bowel is identified as the source of bleeding in as many as one-third of cases,² and UGIB is identified as the source in as many as 11% of patients presenting with hematochezia.³ The most common causes of LGIB are colonic, with diverticular disease being the most common and accounting for 30 to 40% of all cases.⁴ Arteriovenous malformations (AVMs), although extensively described in the literature, are considerably less common causes, accounting for 1 to 4% of cases.⁵ Other significant causative conditions are inflammatory bowel disease (IBD), benign and malignant neoplasms, ischemia, infectious colitis, benign anorectal disease, coagulopathy, use of nonsteroidal antiinflammatory drugs (NSAIDs), radiation proctitis, AIDS, and small bowel disorders.

Presentation and Initial Management

Gastrointestinal bleeding (GIB) may present as severe bleeding with hematemesis (UGIB), hematochezia (UGIB or LGIB), and hypotension; as gradual bleeding with melena (UGIB); or as

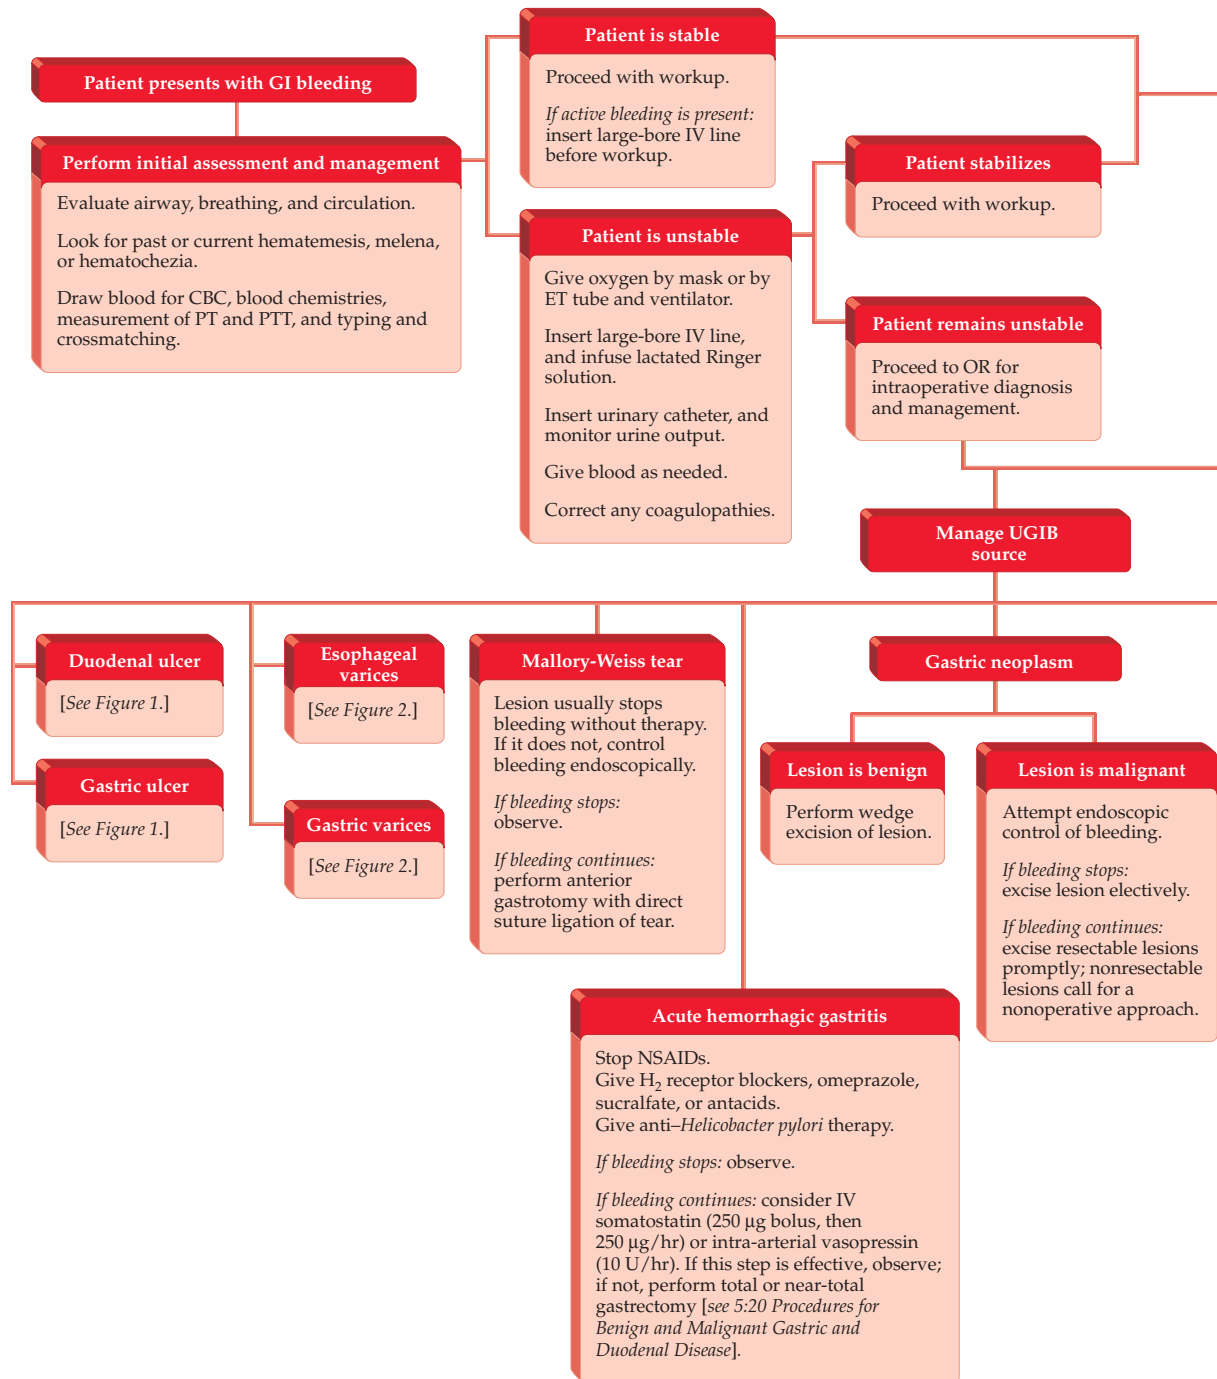

occult bleeding detected by positive tests for blood in the stool. The initial steps in the evaluation of patients with GIB are based on the perceived rate of bleeding and the degree of hemodynamic stability. Hemodynamically stable patients who show no evidence of active bleeding or comorbidities and in whom endoscopic findings are favorable may be treated on an outpatient basis,⁶ whereas patients who show evidence of serious bleeding should be managed aggressively and hospitalized.

The airway, breathing, and circulation should be rapidly assessed, and the examiner should note whether the patient has a history of or currently exhibits hematemesis, melena, or hematochezia. Blood should be drawn for a complete blood count, blood chemistries (including tests of liver function and renal function), and measurement of the prothrombin time and the partial thromboplastin time. Blood should be sent to the blood bank for typing and crossmatching.

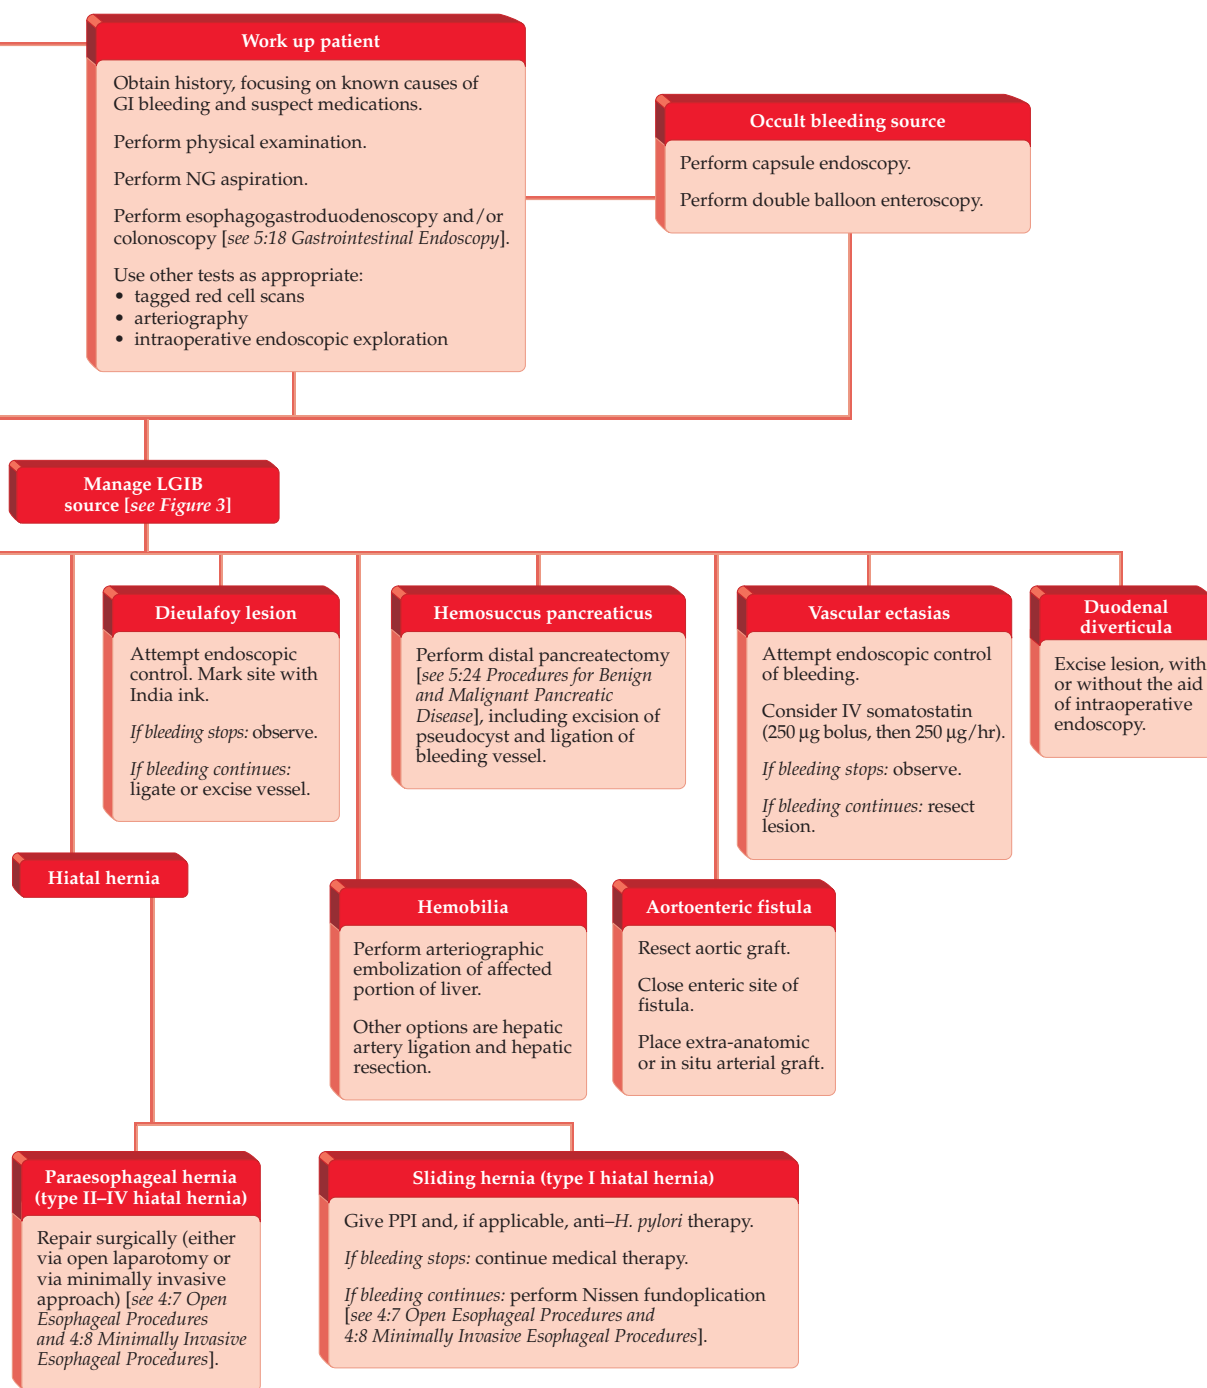

If the patient is stable and shows no evidence of recent or active hemorrhage, the surgeon may proceed with the workup. If, however, the patient is stable but shows evidence of recent or active bleeding, short, large-bore intravenous lines should be placed before workup is begun to ensure that immediate intravenous (IV) access is possible should the patient subsequently become unstable.

If the patient is unstable, he or she should be taken to an intensive care unit and resuscitated immediately. Resuscitation of an unstable patient is begun by establishing a secure airway and ensuring adequate ventilation.⁷ Oxygen should be given, with a low threshold for endotracheal intubation. Much as in trauma resuscitation, either short, large-bore, peripheral IV lines or a single-lumen 8 French catheter in the femoral vein should then be placed, through which lactated Ringer solution or 0.9% normal saline should be infused at a rate high enough to maintain tissue perfusion. A urinary catheter should be inserted and urine output monitored. Blood products should be given as necessary, and any coagulopathies should be corrected. It is all too easy to forget these basic steps in a desire to evaluate and manage massive GI hemorrhage.

Every effort should be made to resuscitate and stabilize the patient sufficiently to allow clinical evaluation and diagnostic testing to help determine the cause of the bleeding and direct subsequent care. Only if the patient remains unstable and continues to bleed despite maximal supportive measures should he or she be taken to the operating room for intraoperative diagnosis as a last resort. If UGIB is the etiology, the

Assessment and Management of Gastrointestinal Bleeding

abdomen should be opened through an upper midline incision, and an anterior gastrotomy should be performed. If inspection does not reveal the source of the bleeding or if bleeding is observed beyond the pylorus, a duodenotomy is made, with care taken to preserve the pylorus if possible. Bleeding from the proximal stomach may be difficult to verify, but it should be actively sought if no other bleeding site is identified. Intraoperative endoscopy should be considered in this situation.

For LGIB, intraoperative options for bleeding-site localization include colonoscopy (to allow for this option, patients should always be placed in the lithotomy position), esophagogastroduodenoscopy (EGD), and transoral passage of a pediatric colonoscope for enteroscopy with simultaneous intraperitoneal assistance for small bowel manipulation [see 5:18 *Gastrointestinal Endoscopy*]. If the bleeding site is identified, directed segmental resection is the procedure of choice: it is associated with rebleeding rates less than 10% and low mortality rates ranging from 0 to 13%.⁸ Blind segmental colectomy should never be performed; it is associated with rebleeding rates as high as 75% and mortality rates as high as 50%.⁹ If the bleeding site still cannot be accurately localized, subtotal colectomy is the procedure of choice. This procedure is associated with high morbidity,¹⁰ which underscores the importance of accurate preoperative localization of bleeding before surgical intervention.

Clinical Evaluation

Only after the initial measures to protect the airway and stabilize the patient have been completed should an attempt be made to establish the cause of the bleeding. The history should focus on known causes of GIB (e.g., previous GIB, peptic ulcer disease, diverticulosis, AVM, esophageal varices, and IBD) and on the possible use of medications that interfere with coagulation (e.g., warfarin, aspirin, and NSAIDs) or alter hemodynamics (e.g., beta blockers and antihypertensive agents). Of particular importance in taking the history is to ascertain the nature and duration of the bleeding, including stool color and frequency. The patient should also be asked about any associated symptoms of potential significance (e.g., abdominal pain, changes in bowel habits, fever, urgency, tenesmus, or weight loss). Knowledge of the patient's cardiac history is useful to assess the patient's ability to withstand varying degrees of anemia.

The physical examination is seldom of much help in determining the exact site of bleeding, but determination of postural vital signs can accurately estimate intravascular volume status. A drop in the orthostatic blood pressure greater than 10 mm Hg or an increase in the pulse rate greater than 10 beats/min indicates that more than 800 mL of blood (> 15% of the total circulating blood volume) has been lost. Marked tachycardia and tachypnea in association with hypotension and depressed mental status indicate that more than 1,500 mL of blood (> 30% of the total circulating blood volume) has been lost. A complete abdominal examination, including digital rectal examination and anoscopy, should be performed as it may reveal jaundice, ascites, or other signs of hepatic

disease; a tumor mass; or a bruit from an abdominal vascular lesion.

A nasogastric tube should be placed for gastric lavage. If lavage yields positive results (i.e., the aspirate contains gross blood or so-called coffee grounds), EGD is indicated. An aspirate that contains copious amounts of bile is strongly suggestive of an LGIB, and the workup proceeds accordingly. The choice is less clear-cut with a clear aspirate. In the absence of bile, such an aspirate cannot rule out a duodenal source for the bleeding. Accordingly, there is some degree of latitude for clinical judgment: depending on the overall clinical picture, the surgeon may choose either to perform EGD to rule out a duodenal bleeding source or to proceed with colonoscopy on the assumption that the source of the bleeding is in the lower GI tract.

UGIB Investigative Tests

ESOPHAGOGASTRODUODENOSCOPY

EGD [see 5:18 *Gastrointestinal Endoscopy*] almost always reveals the source of UGIB; its utility and accuracy have been well documented in the literature.¹¹ Performance of this procedure requires con-

siderable skill: identification of bleeding sites in a blood-filled stomach is far from easy. Hematemesis is an indication for emergency EGD, usually within 1 hour of presentation. If the rate of bleeding is high, saline lavage may be performed to clear the stomach of blood and clots. If the rate of bleeding is moderate or low, as is often the case in patients with melena, urgent EGD is indicated.

EGD is not only an excellent diagnostic tool but also a valuable therapeutic modality. Indeed, most UGIBs may be controlled endoscopically, although the degree of success to be expected in individual cases varies according to the expertise of the endoscopist and the specific cause of the bleeding. Therapeutic endoscopic maneuvers include injection, thermal coagulation, and mechanical occlusion of bleeding sites (clip application or variceal banding). The choice of therapy depends on the cause, the site, and the rate of bleeding.

OTHER UGIB IMAGING

Tagged red blood cell (RBC) scans may confirm the presence of an active bleeding site; however, scans are fairly non-specific with respect to determining the anatomic location of the bleeding.¹² Arteriography may demonstrate that a lesion is present, but it cannot reliably identify a bleeding site unless the bleeding is brisk (> 1 mL/min). Occasionally, arteriography reveals the cause of the bleeding even if the bleeding has stopped. Angiography may also be considered as a therapeutic modality for high-risk surgical patients.⁶ These tests, in conjunction with EGD, should allow the surgeon to establish the cause of UGIB more than 90% of the time.

LGIB Investigative Tests

A number of diagnostic techniques are available for determining the source of LGIB, including colonoscopy [see 5:18 *Gastrointestinal Endoscopy*], radionuclide scanning, computed tomography (CT), and angiography (in the form of selective mesenteric arteriography), enteroscopy, and capsule endoscopy (CE). The goal of these tests is to locate the site of bleeding accurately so that definitive therapy can be properly directed as the potential source ranges from the ligament of Treitz to the anus. Which diagnostic test is chosen for a specific patient depends on several factors, including the hemodynamic stability of the patient, the bleeding rate, patient comorbidities, therapeutic options, and local expertise available. Unlike radionuclide and CT scanning, arteriography and colonoscopy provide a therapeutic option. Arteriography has a lower diagnostic yield and a higher complication rate than colonoscopy does; therefore, it is reasonable to attempt colonoscopy first and to reserve angiography for patients in whom the volume of bleeding is such that colonoscopy would be neither safe nor accurate.¹³

COLONOSCOPY

Several large series that evaluated the diagnostic utility of colonoscopy in patients with LGIB found this modality to be moderately to highly accurate, with overall diagnostic yields ranging from 53 to 97%.^{3,14,15} Those studies that reported morbidity found colonoscopy to be safe, with an average complication rate of 0.5%. Colonoscopy has both a higher diagnostic yield and a lower complication rate than arteriography in this setting and thus would appear to be a more attractive initial test in most circumstances.^{3,16} An argument has been made that colonoscopy should be considered the procedure of choice for structural evaluation of LGIB and that arteriography should be reserved for patients with massive, ongoing bleeding in whom endoscopy is not feasible or colonoscopy fails to reveal the source of the hemorrhage.¹⁷

The merits of colonic purging have been extensively debated in the literature.^{3,18} Although no firm conclusion has been reached, adequate colonic purging may improve both the diagnostic yield and the safety of colonoscopy. Given the absence of any definitive data suggesting that colonic purging either reactivates or increases bleeding, one should consider administering an oral purge after the patient has been adequately resuscitated.

If the entire colon has been adequately visualized and no source for the bleeding has been identified, the ileum should be intubated; fresh blood in this region suggests a possible small bowel source. If no active bleeding is observed in the ileum, upper GI endoscopy should be performed to rule out a UGIB site.

When colonoscopy identifies a bleeding source, endoscopic treatment may be an option [see 5:18 *Gastrointestinal Endoscopy*]. Endoscopic modalities used to treat LGIB include use of thermal contact probes, laser photocoagulation,

electrocauterization, injection of vasoconstrictors, application of metallic clips, and injection sclerotherapy. The choice of a specific modality often depends on the nature of the offending lesion and on the expertise and resources available locally. A 1995 survey of members of the American College of Gastroenterology found that endoscopic therapy was used in 27% of patients presenting with LGIB.¹⁹

RADIONUCLIDE SCANNING

Radionuclide scanning is highly sensitive for lower LGIB, capable of detecting bleeding at rates as slow as 0.1 to 0.4 mL/min.²⁰ The patient's RBCs are labeled with technetium-99m (^{99m}Tc), which can be detected on images as long as 24 to 48 hours after injection [see Figure 1]. The high sensitivity of ^{99m}Tc-labeled RBC scanning—80 to 98%—is well attested, but there is considerable disagreement in the literature with regard to its specificity in identifying the anatomic site of bleeding.^{21,22} For example, on the one hand, a 1997 study found radiolabeled RBC scanning to be 97% accurate for localizing bleeding in 37 patients undergoing surgical resection²²; on the other hand, a 1990 study reported a 42% rate of incorrect resection when surgical therapy was based solely on this modality.²¹ In 2005, one group retrospectively reviewed 127 bleeding scans in an effort to identify factors that might predict a positive scan.²³ The investigators found that tagged RBC scans were 48% accurate in localizing bleeding sites later confirmed by endoscopy, surgery, or pathologic evaluation. Multivariate analysis demonstrated that both the number of units of blood transfused in the 24 hours preceding the scan and the lowest recorded hematocrit differed significantly between patients with positive scans and those with negative scans. However, the clinical significance of a positive scan was unclear in this study in that the rate of endoscopy was not significantly different between patients who had positive scans and those who did not.

To date, no prospective, randomized trials have compared radionuclide scanning with colonoscopy as the initial diagnostic procedure for patients with lower GI hemorrhage. Given that radionuclide scanning has no therapeutic intervention capabilities, its best use is in patients with non-life-threatening LGIB as a prelude and a guide to mesenteric angiography after active hemorrhage has been confirmed.

Radionuclide scanning is also useful for diagnosing Meckel diverticulum, a rare cause of LGIB. Patients are injected with ^{99m}Tc pertechnetate, which is taken up by the ectopic gastric mucosa. Although studies in the pediatric population have demonstrated high diagnostic accuracy, the sensitivity of the scan is only 60 to 70% in the adult population.²⁴

ANGIOGRAPHY

Selective mesenteric arteriography is somewhat less sensitive than radionuclide scanning for lower GI hemorrhage: bleeding must be occurring at a rate of at least 1.0 to 1.5 mL/min to be detectable with this test.²⁵ The procedure involves percutaneous placement of a transfemoral arterial catheter for evaluation of the superior mesenteric, inferior mesenteric, and celiac arteries. A positive test result is defined as extravasation of contrast into the lumen of the bowel. Once the bleeding vessel has been localized angiographically, the area

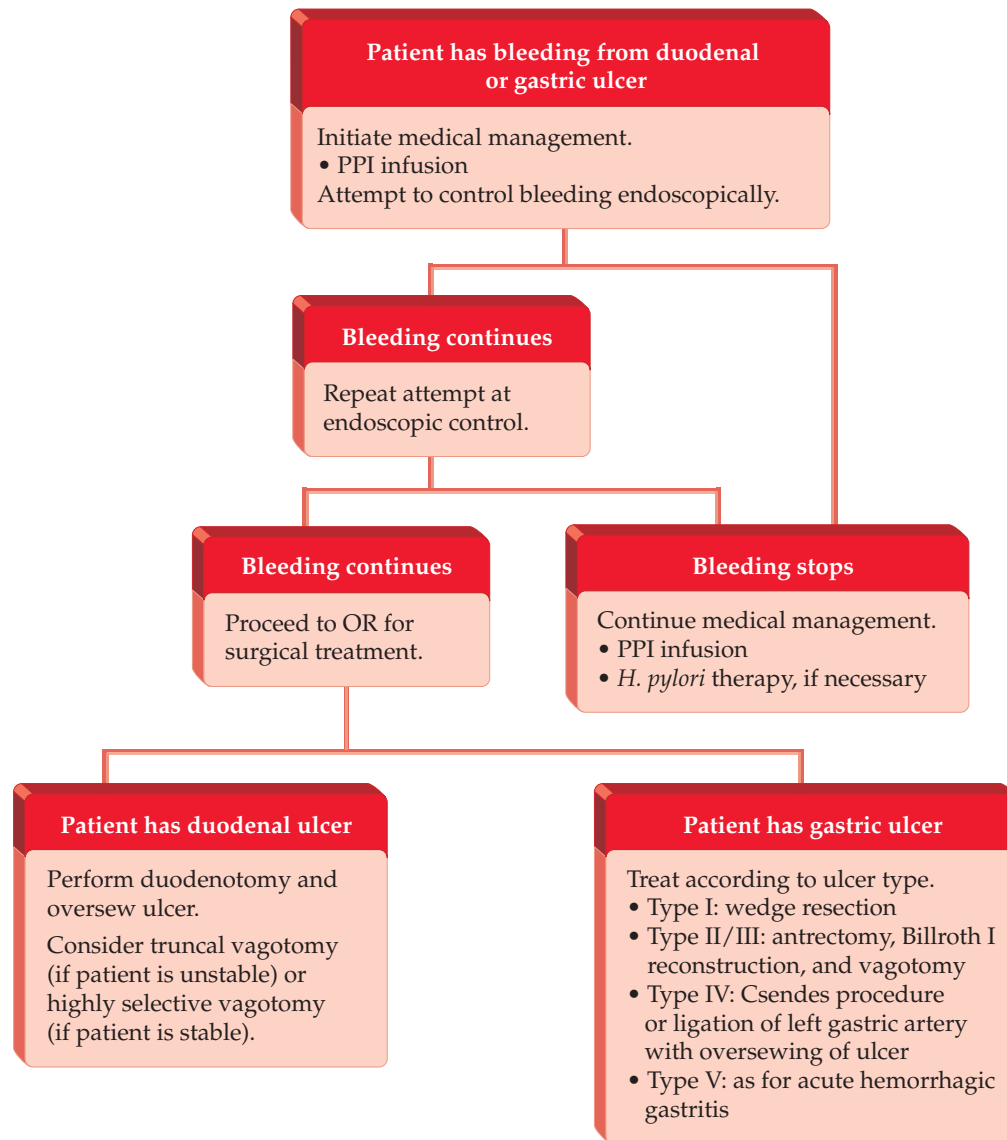

Figure 1 An algorithm for management of bleeding from duodenal or gastric ulcers. OR = operating room; PPI = proton pump inhibitor.

must be marked so that it can be successfully identified intra-operatively; this is commonly accomplished by infusing methylene blue into the bleeding artery [see Figure 2].²⁶

In several large series, the overall diagnostic yield of arteriography ranged from 27 to 67%.^{8,22,27,28} The complication rate for arteriography performed for LGIB ranges from 2 to 4%.^{2,26} Reported complications include contrast allergy, renal failure, bleeding from arterial puncture, and embolism from a dislodged thrombus.¹⁷ Diagnostic use of angiography in patients with LGIB can often be followed by angiographic therapy. The two main angiographic treatment options are intra-arterial injection of vasopressin and transcatheter embolization.

Vasopressin acts to control bleeding by causing arteriolar vasoconstriction and bowel wall contraction. Once the bleeding site has been localized angiographically, the catheter is positioned in the main trunk of the vessel. Infusion of

vasopressin is initiated at a rate of 0.2 U/min and can be increased to a rate of 0.4 U/min. Within 20 to 30 minutes, angiography is performed again to determine whether the bleeding has ceased. If the bleeding is under control, the catheter is left in place and vasopressin is continuously infused for 6 to 12 hours. If the bleeding continues to be controlled, infusion is continued for an additional 6 to 12 hours at 50% of the previous rate. Finally, vasopressin infusion is replaced by continuous saline infusion, and if bleeding does not recur, the catheter is removed.²⁹

The vasoconstrictive action of vasopressin can have deleterious systemic side effects, including myocardial ischemia, peripheral ischemia, hypertension, dysrhythmias, mesenteric thrombosis, intestinal infarction, and death. Occasionally, simultaneous intravenous administration of nitroglycerin is necessary to counteract these systemic effects. The reported success rate of vasopressin in controlling LGIB ranges from

60 to 100%, and the incidence of major complications ranges from 10 to 20%.^{30–32} Rebleeding rates as high as 50% have been reported.^{30,31}

An alternative for patients with coronary vascular disease, severe peripheral vascular disease, or other comorbidities that prevent safe administration of vasopressin is transcatheter embolization. In this technique, a catheter is superselectively placed into the identified bleeding vessel and an embolizing agent (e.g., a gelatin sponge, a microcoil, polyvinyl alcohol particles, or a balloon) is injected. Several small series found this technique to be 90 to 100% successful at stopping bleeding.^{32–34} Equally impressive was the finding that the rebleeding rates in these series were 0%. The complication rates of this procedure are generally reasonable as well; however, intestinal infarction has been reported.^{8,35}

The use of small microcatheters and the ability to superselectively embolize individual vessels have reduced the potential for ischemic perforation. It is possible that as more experience is gained with these techniques, superselective embolization may replace catheter-directed vasoconstrictive therapy, thus obviating the potential deleterious systemic effects of vasopressin administration. Some researchers have suggested that with the exception of cases of diffuse bleeding lesions or cases whose demands exceed the technical limitations of superselective catheterization, embolization therapy should be the first choice for angiographic treatment of LGIB.^{35,36}

In a minority of patients, obscure bleeding persists despite negative findings from endoscopy, mesenteric arteriography, and radiolabeled RBC scanning. This obscure bleeding presents a considerable diagnostic challenge, which some investigators have proposed addressing by means of so-called provocative angiography.³⁷ Provocative angiography involves the use of short-acting anticoagulant agents (unfractionated heparin, vasodilators, thrombolytics, or combinations thereof) in association with angiography. Once the bleeding point has been localized (in up to 89% of cases in a recent study),³⁸ superselective embolization can be attempted or methylene blue is injected and the patient is immediately brought to the operating room (OR) for surgical treatment.

COMPUTED TOMOGRAPHY

With the ongoing improvements in high-speed abdominal CT scanning, interest has been growing in the evaluation of GIB with CT.³⁹ Helical CT scanners can provide direct or indirect evidence of the source of GIB. Typical findings that can facilitate localization of bleeding sites include spontaneous hyperdensity of the peribowel fat, contrast enhancement of the bowel wall, vascular extravasation of the contrast medium, thickening of the bowel wall, polyps, tumors, and vascular dilatation.

CT evaluation of GIB has several noteworthy advantages: the scanners typically are readily available, mobilization of special teams or units is not required, the scans can be completed rapidly in the emergency department, and bowel preparation is unnecessary. In one experimental study, CT scanners were able to detect arterial bleeding at rates as low as 0.07 mL/min, which suggests that CT scanning is more sensitive than angiography for this purpose.⁴⁰ In addition, CT scans are noninvasive and carry little morbidity. Unfortunately, like radionuclide scanning, CT has no therapeutic capability.

A 2003 study of 19 patients with GI hemorrhage compared triphasic helical CT evaluation with colonoscopy and surgery for localization of bleeding sites.⁴⁰ In this series, 5 patients had small bowel bleeding sites, and 14 patients had colonic sites. Helical CT scanning correctly identified 4 of the 5 small bowel lesions and 11 of the 14 colonic lesions. These findings, although preliminary, suggest that CT is a potentially valuable evaluation method in certain cases of GIB. Perhaps CT scanning can eventually replace radionuclide scanning, which is often inaccurate. One potential drawback to the use of CT in this setting is the excessive dye load if angiography is employed as well.

ENTEROSCOPY

When other tests fail to locate a bleeding source, enteroscopy may be helpful to localize the LGIB. This procedure can be carried out in several ways. It can be performed purely endoscopically with a pediatric colonoscope. Termed “push” enteroscopy, this approach generally requires a high level of skill on the part of the endoscopist in that the lack of retroperitoneal attachments of the small intestine makes endoscopic navigation extremely challenging. In most cases, only the proximal 150 cm of the small intestine can be evaluated in this way. Depending on the indication and on the technique employed, the diagnostic yield from push enteroscopy has ranged from 13 to 78%.⁴¹ Typically, yields are highest (40 to 60%) in patients with significant GI hemorrhage.

Recently, double-balloon enteroscopy (DBE) has evolved as an effective method of identifying and endoscopically treating occult LGIB. Using this technique, the entire length of the small intestine can be examined in up to 50% of cases using combined antegrade (transoral) and retrograde (transanal) insertion by milking the bowel in a push/pull technique between two balloons.⁴² A recent study demonstrated that 66% of occult bleeding sources were identified using DBE. DBE should be considered the first choice in stable patients with occult active bleeding.

CAPSULE ENDOSCOPY

Another option for stable patients with occult GIB is CE, in which a miniature camera is swallowed and intermittent images are taken along the entire length of the GI tract as the capsule advances. Recent studies, including a prospective, blinded trial and several meta-analyses, have demonstrated that the diagnostic yield of CE is similar to that of DBE, although CE does not allow for therapeutic intervention.^{42–44} Because it is less invasive, however, CE should be considered the first choice in stable patients in whom occult bleeding has stopped.

Discussion and Management of Specific Sources of UGIB

DUODENAL ULCER

The development of effective medical regimens for controlling uncomplicated duodenal ulcers has led to a drastic reduction in the number of elective surgical procedures performed for this purpose. Nevertheless, the incidence of bleeding from duodenal ulcers that is

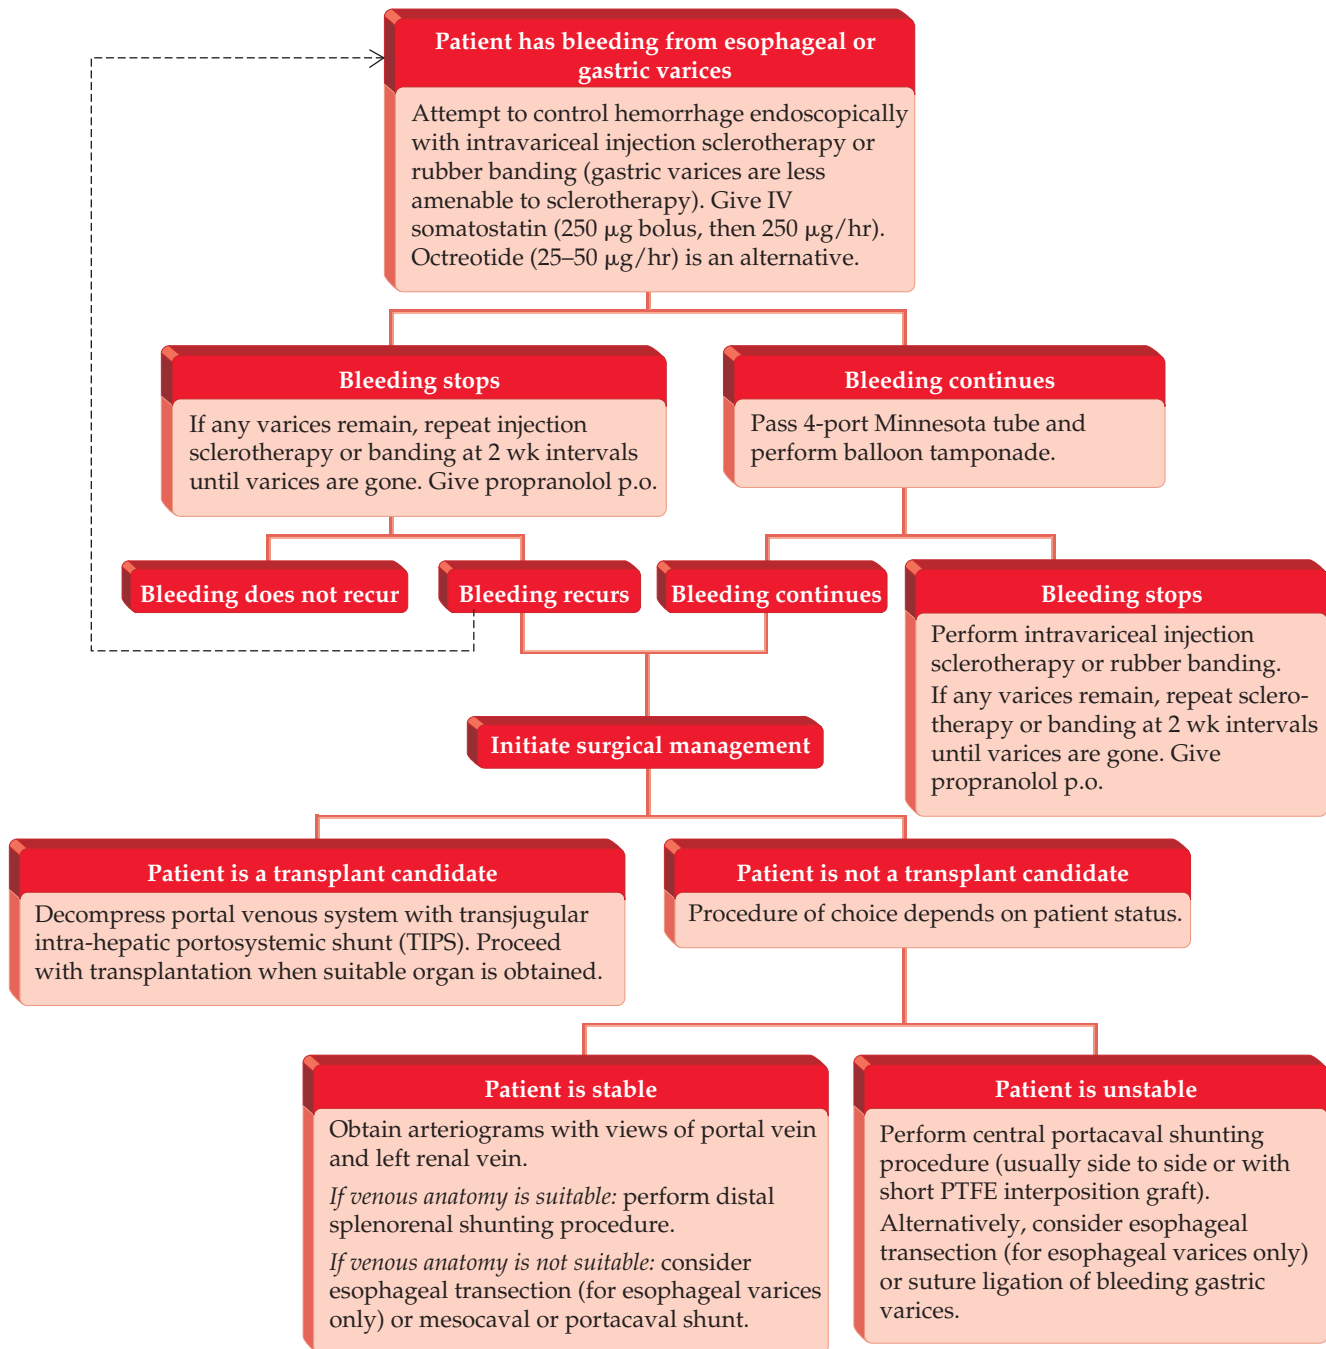

Figure 2 An algorithm for management of bleeding from esophageal or gastric varices.
IV = intravenous; PTFE = polytetrafluoroethylene.

severe enough to necessitate emergency endoscopic or operative intervention has not decreased over the past decade.⁴⁵

Once EGD has demonstrated that a duodenal ulcer is the source of the bleeding, the first question that must be addressed is whether active bleeding is present. If it is, an attempt should be made to control the hemorrhage endoscopically [see Figure 1]. Because ongoing blood loss eventually leads to coagulopathies, the surgeon must exercise good judgment in deciding how long to pursue endoscopic treatment before concluding that such treatment has failed and that surgical treatment is necessary. In general, substantial bleeding (6 units or more) or bleeding that is not controlled

endoscopically is an indication for surgical intervention. Likewise, ongoing hemorrhage in a hemodynamically unstable patient (especially an elderly one) calls for immediate surgical therapy. In addition, certain patients whose bleeding is controlled endoscopically (e.g., those with a visible vessel, active bleeding, or an adherent clot,⁴⁶ as well as those with giant ulcers) should be strongly considered for surgical therapy.

If bleeding is controlled endoscopically, then a proton pump inhibitor (PPI), such as pantoprazole, should be given intravenously, either in a bolus twice daily or by continuous infusion.⁴⁷ In addition, antibiotic therapy directed against *Helicobacter pylori* (e.g., a 14-day course of metronidazole,

500 mg p.o., t.i.d.; omeprazole, 20 mg p.o., b.i.d.; and clarithromycin, 500 mg p.o., b.i.d.) should be considered if the organism is present; such therapy has been shown to reduce rebleeding rates after antacid medication has been stopped.⁴⁸ Food need not be withheld unless the likelihood of rebleeding is high, because resumption of oral feeding does not appear to affect rebleeding rates.⁴⁹ If bleeding recurs despite medical and endoscopic therapy, a second attempt at endoscopic control should be made. Repeat endoscopic treatment reduces the need for surgery without increasing the risk of death and is associated with fewer complications than is surgery.⁵⁰

Surgical management may be accomplished either laparoscopically or via an open approach [see 5:20 *Procedures for Benign and Malignant Gastric and Duodenal Disease*]. The latter begins with an upper midline incision. The duodenum is mobilized, and an anterior longitudinal duodenotomy is performed over the site of the ulcer. The bleeding vessel, which is usually on the posterior wall of the first portion of the duodenum, is ligated with nonabsorbable sutures at sites proximal and distal to the bleeding point. A third stitch is placed posterior to the bleeding vessel. Pains must be taken to avoid injury to the common bile duct during the placement of these sutures. The duodenotomy is then closed. If a truncal vagotomy is to be performed, the duodenotomy should extend through the pylorus and be closed transversely to perform a pyloroplasty. Frozen section to confirm the presence of nerve tissue is helpful for ensuring that the vagotomy is complete.

The recommendation for truncal vagotomy is based on data from studies done before PPIs and *H. pylori* therapy came into use. Subsequent studies and a 2004 Cochrane review that evaluated rebleeding rates with current medical regimens demonstrated much lower rebleeding rates.⁵¹ Furthermore, it seems probable that long-term PPI therapy (the medical equivalent of vagotomy), in conjunction with eradication of *H. pylori* and avoidance of NSAIDs, should reduce rebleeding rates significantly. Studies from the United States⁴⁵ and the United Kingdom⁵² have shown that a vagotomy is performed less than 50% of the time during surgical treatment of an acute bleeding duodenal ulcer. Therefore, although there are no prospective, randomized studies to support it, one may consider an alternative treatment approach in patients who have not been receiving ulcer therapy before the bleeding began—namely, ligation of the bleeding vessel, postoperative administration of PPIs, and *H. pylori* therapy. This approach avoids the complications associated with truncal vagotomy.

Another option for preventing postvagotomy symptoms when operating on stable patients for bleeding duodenal ulcer is to perform a highly selective vagotomy (HSV) [see 5:20 *Procedures for Benign and Malignant Gastric and Duodenal Disease*]. This procedure is considered preferable to truncal vagotomy because of the decreased incidence of gastric atony, alkaline reflux gastritis, dumping, and diarrhea; however, HSV is associated with a higher recurrence rate than is truncal vagotomy and takes significantly longer to perform.⁵³

GASTRIC ULCER

Gastric ulcers are classified according to their location and to the role (if any) that gastric acid hypersecretion plays in their development. Type I ulcers are located on the lesser curvature and are not associated with acid secretion. Type II ulcers are associated with high acid secretion and are located

on the lesser curvature, occurring in synchrony with duodenal ulcers. Type III ulcers are also associated with acid hypersecretion but occur in the prepyloric region. Type IV ulcers are not associated with acid secretion and are located in the cardia near the esophagogastric junction. Type V ulcers are diffuse and are related to the use of medications (e.g., NSAIDs) [see *Acute Hemorrhagic Gastritis, below*].

Bleeding is less common than with duodenal ulcers, but initial management of a bleeding gastric ulcer is the same as that of a duodenal ulcer (i.e., endoscopic control) [see *Figure 1*]. To prevent aggravation of the bleeding, early biopsy generally is not recommended; repeat endoscopy and biopsy are done at a later date. The indications for emergency surgical intervention for gastric ulcers are the same as those for duodenal ulcers.

Bleeding gastric ulcers that necessitate operative intervention should be treated with resection. For type I ulcers, wedge resection is typically performed. For type II and III ulcers, the usual approach consists of antrectomy with Billroth I reconstruction and truncal vagotomy [see 5:20 *Procedures for Benign and Malignant Gastric and Duodenal Disease*]. Type IV ulcers can pose a technical challenge as a consequence of their close proximity to the esophagogastric junction. A distal gastrectomy with a tongue-shaped extension upward along the lesser curvature to incorporate the ulcer, followed by a Roux-en-Y reconstruction (the Csendes procedure), is often required.⁵⁴ Another option is ligation of the left gastric artery, followed by biopsy and oversewing of the ulcer.

ESOPHAGEAL VARICES

The value of endoscopy in the diagnosis and management of variceal bleeding cannot be overemphasized. Even in patients with known varices, the site of bleeding is frequently nonvariceal; endoscopy is therefore essential.⁵⁵ If bleeding varices are identified, rubber banding or intravariceal sclerotherapy with a sclerosing agent (1.5% sodium tetradecyl sulfate, ethanolamine, sodium morrhuate, or absolute alcohol) is performed [see *Figure 2*].⁵⁶ If these measures do not control the hemorrhage, balloon tamponade is indicated.⁵⁷ Patients who are to undergo this procedure require an endotracheal tube. The preferred tube to use for balloon tamponade is the four-port Minnesota tube, although the Sengstaken-Blakemore tube is also acceptable. The Minnesota tube has a gastric balloon, an esophageal balloon, and aspiration ports for the esophagus and the stomach. The gastric balloon is inflated first and placed on traction. If the bleeding is not controlled, the esophageal balloon is then inflated to a set pressure. The pressure in the balloons should be released in 24 to 48 hours to prevent necrosis of the esophageal or the gastric wall. Successful balloon tamponade is followed by endoscopic variceal injection or variceal banding.

Intravenous somatostatin (250 µg bolus, followed by infusion of 250 µg/hr) should be administered in conjunction with the above-mentioned steps. Vasopressin (10 U/hr) may also be given; however, it causes diffuse vasoconstriction, and nitroglycerin may be required to alleviate cardiac side effects. Somatostatin has proved superior to placebo in controlling variceal hemorrhage when used in conjunction with endoscopic sclerotherapy.⁵⁸ It is as effective as vasopressin while giving rise to fewer side effects. Octreotide, a synthetic analogue of somatostatin, shares many of the properties of

Figure 3 An algorithm for management of lower gastrointestinal bleeding (LGIB). AVM = arteriovenous malformation; IV = intravenous; OR = operating room; TIPS = transjugular intrahepatic portosystemic shunt.

somatostatin but perhaps not all. Both agents decrease secretion of gastric acid and pepsin; however, the decreased gastric blood flow observed with somatostatin administration has not been reported with octreotide administration. Nevertheless, some clinicians in the United States elect to use octreotide (25 to 50 µg/hr) in place of IV somatostatin because the former tends to be more widely available. Several prospective, randomized trials showed that propranolol (40 mg b.i.d., p.o.) decreased the incidence of first-time variceal bleeding and the incidence of recurrent variceal bleeding.^{59,60} Propranolol should not be used during active bleeding but should be started once bleeding stops.

After the acute variceal bleeding has been controlled, any remaining varices should be subjected to injection sclerotherapy or banding at 2-week intervals until they too are obliterated.

The main indications for surgical intervention in patients with bleeding esophageal varices are uncontrolled hemorrhage and persistent rebleeding despite endoscopic and medical therapy. When such intervention is considered, it is essential to determine whether the patient is a transplant candidate. If so, operation should be avoided and bleeding managed by decompressing the portal venous system with a transjugular intrahepatic portosystemic shunt (TIPS) [see 5:10 Portal Hypertension]. TIPS significantly reduces rebleeding rates, but it poses a risk of encephalopathy.⁶¹

If the patient is not a transplant candidate and is not actively bleeding, a distal splenorenal shunt (DSRS) is preferable.⁶² Arteriograms with views of the portal vein and the left renal vein are obtained to assess for suitable anatomy. Alternatively, CT angiography with three-dimensional reconstruction may be performed. If the venous anatomy is suitable—that is, if the diameter of the splenic vein is greater than 0.75 cm (preferably greater than 1.0 cm) and the vein is within one vertebral body of the renal vein on venography—a DSRS procedure should be feasible. If the venous anatomy is not suitable, then esophageal transection, a mesocaval venous graft, or a portacaval shunt is required.

In the emergency setting, a central portacaval shunt, usually in a side-to-side orientation or with a short polytetrafluoro-

ethylene (PTFE) interposition graft, may be placed. Esophageal transection is also a reasonable choice. This procedure is associated with a lower incidence of encephalopathy than a portacaval shunting procedure; however, it is associated with higher rates of rebleeding (particularly late rebleeding), and it can be difficult to perform when active bleeding is present. Suture ligation of the bleeding varices with devascularization (the Sugiura procedure) [see 5:10 Portal Hypertension] should also be considered.

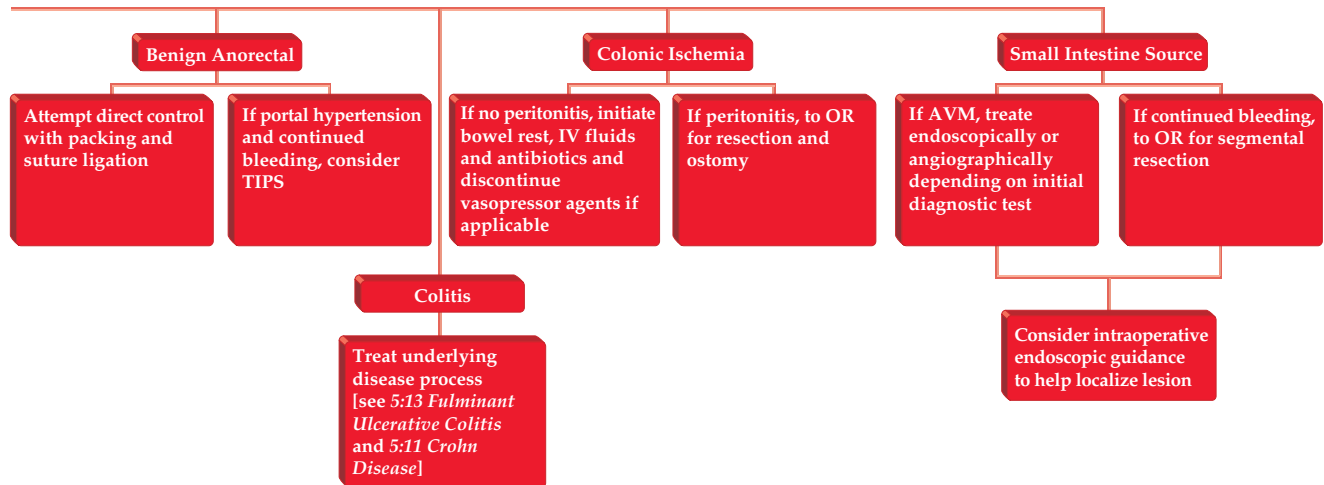

In general, prognosis is related to the underlying liver disease. For example, patients with varices that are secondary to chronic extrahepatic portal venous or splenic venous occlusion generally have a much better prognosis than those whose portal hypertension is secondary to hepatic parenchymal causes. The severity of the cirrhosis also determines short-term and long-term survival and may influence the decision whether to perform a shunting procedure. For varices that are secondary to splenic vein thrombosis (sinistral portal hypertension), splenectomy is usually curative; the procedure may be performed laparoscopically [see 5:25 Splenectomy].⁶³

GASTRIC VARICES

Gastric varices are managed in much the same way as esophageal varices [see Figure 2], although they are less amenable to sclerotherapy.⁶⁴ Other endoscopic treatments (e.g., ligation or sclerotherapy plus ligation) and interventional radiologic treatments (e.g., TIPS or intravascular balloon occlusion) should be considered before surgical management (i.e., DSRS, portosystemic shunting, or suture ligation with gastric devascularization). If the patient is a suitable candidate, liver transplantation may be performed as an alternative to shunting.

MALLORY-WEISS TEARS

Mallory-Weiss tears are linear mucosal tears at the esophagogastric junction that are usually caused by vomiting. Any patient who presents with vomiting that initially is not bloody but later turns so should be suspected of having a Mallory-Weiss tear. As a rule, these lesions stop bleeding without

therapy. If bleeding is substantial or persistent, however, endoscopic injection, clipping, banding, or coagulation may be necessary.^{65,66} In rare instances, the tear will have to be oversewn at operation. This is accomplished via an anterior gastrotomy and direct suture ligation of the tear.

ACUTE HEMORRHAGIC GASTRITIS

Bleeding from gastritis is virtually always managed medically with H₂ blockers, PPIs, sucralfate, or antacids (either alone or in combination), along with antibiotics if *H. pylori* is present.⁶⁷ Somatostatin may be beneficial. Sometimes, administration of vasopressin via the left gastric artery is needed to control bleeding. In rare cases, total or near-total gastrectomy [see 5:20 *Procedures for Benign and Malignant Gastric and Duodenal Disease*] is required; however, the mortality associated with this operation in this setting is high. Stress ulcer prophylaxis in severely ill or traumatized patients is essential to prevent this problem.⁶⁸ The gastric pH should be kept as close to neutral as possible. If the gastritis is relatively mild, a biopsy specimen should be obtained and tested for *H. pylori*. Treatment consists of acid reduction and *H. pylori* therapy.

NEOPLASMS

Benign tumors of the upper GI tract (e.g., gastrointestinal stromal tumors [GISTs], hamartomas, and hemangiomas) occasionally bleed [see 5:8 *Tumors of the Stomach, Duodenum, and Small Bowel*]. Wedge excision of the offending lesion is the procedure of choice. GISTs (previously classified as leiomyomas or leiomyosarcomas) run the gamut from benign to highly aggressive. They typically present as a submucosal mass that may cause bleeding as a result of mucosal ulceration. The bleeding may be treated with wedge excision of the tumor,

which can be challenging when the GIST is located in the gastric cardia. Such excision can often be accomplished laparoscopically [see 5:20 *Procedures for Benign and Malignant Gastric and Duodenal Disease*] or even through a laparoscopic intragastric approach.⁶⁹ Some surgeons now perform full-thickness wedge resections endoscopically with the use of a flexible stapler.⁷⁰

Bleeding from malignant neoplasms, whether early stage or late stage, generally can be controlled initially by endoscopic means; however, rebleeding rates are high.⁷¹ If the lesion is resectable, it should be excised promptly once the patient is stable (provided that it has been appropriately staged). If disease is advanced, however, surgical options are limited, and a nonoperative approach, although necessarily imperfect, is preferable.

HIATAL HERNIA

Not infrequently, the source of chronic enteric blood loss is a hiatal hernia. Major bleeding is rare in this condition but may occur as a result of linear erosions at the level of the diaphragm (Cameron lesions),⁷² gastritis within the hernia, or torsion of a paraesophageal hernia. Endoscopy is generally diagnostic, although the sources of chronic blood loss are not always obvious. Recognition that the bleeding derives from a Cameron lesion should incline the surgeon toward operative intervention [see 4:7 *Open Esophageal Procedures* and 4:8 *Minimally Invasive Esophageal Procedures*]; this lesion is usually mechanically induced and therefore tends to be less responsive to antacid therapy.

Chronic bleeding from a type I hiatal hernia should be treated initially with a PPI. *H. pylori* therapy should be added if biopsy shows this organism to be present. Operative management (i.e., laparoscopic Nissen fundoplication [see 4:8 *Minimally Invasive Esophageal Procedures*]) should be considered for fit patients who have complications associated with their hiatal hernia and for all symptomatic patients with type II, III, or IV hiatal hernias (laparoscopic paraesophageal hernia repair).⁷³

DIEULAFOY LESION

A Dieulafoy lesion is the rupturing of a 1 to 3 mm bleeding vessel through the gastric mucosa without surrounding ulceration. This lesion is most commonly found high on the lesser curvature, but it can also occur anywhere throughout the GI tract. Histologic studies have not revealed any intrinsic abnormalities either of the mucosa or of the vessel.

Initial treatment consists of either endoscopically based coagulation of the bleeding vessel with a heater probe or mechanical control with clips or rubber bands; local injection of epinephrine may help control acute hemorrhage while this is being done. In skilled hands, endoscopic therapy has a 95% success rate, and long-term control is excellent. If endoscopic therapy fails, surgical options, including ligation or excision of the vessel involved, come into play.⁷⁴ Having the endoscopist mark the site with India ink is helpful for localization.

HEMOBILIA

Hemobilia should be suspected in all patients who present with the classic triad of epigastric and right upper quadrant pain, GIB, and jaundice; however, only about 40% of patients with hemobilia present with the entire triad. Endoscopy demonstrating blood coming from the ampulla of Vater points to a source in the biliary tree or the pancreas (hemosuccus pancreaticus).

Arteriography may provide the definitive diagnosis: a bleeding tumor, a ruptured artery from trauma, or another cause. Arteriographic embolization of the affected portion of the liver is the preferred treatment option; hepatic artery ligation (selective if possible) or hepatic resection [see 5:23 *Hepatic Resection*] may be required.

HEMOSUCCUS PANCREATICUS

Bleeding into the pancreatic duct, generally from erosion of a pancreatic pseudocyst into the splenic artery, is signaled by upper abdominal pain followed by hematochezia.⁷⁵ If endoscopy is performed when hematochezia is present, the bleeding site may not be seen; however, if endoscopy is performed when pain is first noted, blood may be seen coming from the ampulla of Vater. The combination of significant GIB, abdominal pain, a history of alcohol abuse or pancreatitis, and hyperamylasemia should suggest the diagnosis. If there are no pancreatitis-related indications for surgery, angiographic embolization can be definitive treatment.⁷⁶ If there are pancreatitis-related indications for operation, angiographic embolization may allow an elective operative procedure based on the structural changes observed in the pancreas. If embolization fails, pancreatic resection is usually required, often on an emergency basis [see 5:24 *Procedures for Benign and Malignant Pancreatic Disease*].

AORTOENTERIC FISTULA

Aortoenteric fistulas may occur spontaneously as a result of rupture of an aortic aneurysm or perforation of a duodenal lesion (primary); more often, they arise after aortic surgery (secondary).⁷⁷ A common initial manifestation of an aortoenteric fistula is a small herald bleed that is followed a few days later by a massive hemorrhage. Patients often present with the triad of GI hemorrhage, a pulsatile mass, and infection; however, not all of these symptoms are invariably present.

A high index of suspicion facilitates diagnosis. Endoscopy may show an aortic graft eroding into the enteric lumen, but this is an uncommon finding. CT scanning is the procedure of choice for diagnosis. The finding of air around the aorta or the aortic graft is diagnostic and is an indication for emergency exploration. The preferred surgical treatment is resection of the graft with extra-abdominal bypass. Some authorities, however, advocate resection of the graft with in situ graft replacement.⁷⁸ Some now advocate endovascular stent repair for high-risk patients without evidence of infection.⁷⁹

VASCULAR ECTASIAS

Vascular ectasias (also referred to as vascular dysplasia, angiodysplasia, angiomas, telangiectasia, and AVMs) may bleed briskly. As a rule, gastric lesions can be readily identified and the bleeding controlled by endoscopic means.⁸⁰ Lesions that continue to bleed, either acutely or chronically, despite endoscopic measures should be excised. Some patients have multiple and extensive lesions that necessitate resection of large portions of the stomach. Pharmacotherapy and hormone therapy have been tried; the results have been mixed.

DUODENAL DIVERTICULA

Duodenal diverticula are rare causes of UGIB. Accurate identification of a bleeding site within a given diverticulum is difficult, but an attempt should be made to accomplish this by means of per oral enteroscopy or video-CE. Excision is the preferred treatment and is accomplished by means of segmental resection.⁸¹ Great care must be taken in the treatment of duodenal diverticula in the region of the ampulla of Vater to ensure that the pancreatic duct and the bile ducts are not injured during excision.

Discussion and Management of Specific Sources of LGIB

DIVERTICULOSIS

The vast majority of colonic diverticula are actually false diverticula (pseudodiverticula) that contain only serosa and mucosa [see 5:12 *Diverticulitis*]. They occur at weak points in the colonic wall where the vasa recta penetrate the muscularis to supply the mucosa; as the diverticulum expands, these vessels are displaced. A 1976 anatomic study of colonic specimens from patients with diverticular bleeding used angiography to demonstrate that in all cases, the vasa recta overlying the diverticulum ruptured into the lumen of the diverticulum, not into the peritoneum.⁸²

It has been estimated that approximately 17% of patients with colonic diverticulosis experience bleeding, which may range from minor to severe and life-threatening. Fortunately, most diverticular hemorrhages stop spontaneously. In one series, surgery was unlikely to be necessary if fewer than 4 units of packed RBCs were transfused in a 24-hour period, whereas 60% of patients receiving more than 4 units of packed RBCs in a 24-hour period required surgical intervention.⁸³ Semielective surgical therapy is usually offered after a second diverticular bleeding episode because once a second such episode has occurred, the risk that a third will follow exceeds 50%. In a series of 83 conservatively managed cases of

diverticular disease, the predicted yearly recurrence rates were 9% at 1 year, 10% at 2 years, 19% at 3 years, and 25% at 4 years.⁸⁴

In general, patients who require more than 4 units of blood in a 24-hour period to remain hemodynamically stable, who have not stopped bleeding after 72 hours, or who experience rebleeding within 1 week after an initial episode should undergo surgery.¹⁸

Endoscopic treatment of diverticular hemorrhage can be difficult because of the high bleeding rate and the location of the bleeding point within the diverticulum. In 2000, one group of investigators reported their experience with endoscopic therapy for severe hematochezia and diverticulosis in a prospective series of 121 patients.⁸⁵ In this series, none of the patients treated endoscopically with epinephrine injections, bipolar coagulation, or both required surgery and none experienced recurrent bleeding episodes. A 2001 study from another group, however, reported high rates of recurrent bleeding episodes in both the early and the late posttreatment periods.⁸⁶ In the absence of prospective, randomized trials, it is difficult to draw definitive conclusions about the utility of endoscopic therapy in treating diverticular hemorrhage.

COLONIC AVMS

The term *arteriovenous malformation* includes vascular ectasias, angiomas, and angiodysplasias. AVMs are ectatic blood vessels seen in the mucosa and submucosa of the GI tract. They are degenerative lesions of the GI tract, occurring more frequently with advancing age.¹⁸ In patients older than 50 years, the incidence of colonic AVMs is estimated to range from 2 to 30%.⁸⁷

Colonic AVMs are believed to derive from chronic colonic wall muscle contraction, which leads to chronic partial obstruction of the submucosal veins, causing the vessels to become dilated and tortuous. This process eventually renders the precapillary sphincters incompetent, resulting in direct arterial-venous communication. Colonic AVMs are most commonly found in the cecum. They have been associated with several systemic diseases, including atherosclerotic cardiovascular disease, aortic stenosis, chronic renal disease, collagen vascular disease, von Willebrand disease, chronic obstructive pulmonary disease, and cirrhosis of the liver; to date, however, no definite causal relationship to any of these conditions has been established.²¹

The diagnosis of a colonic AVM is made at the time of angiography or colonoscopy. During angiography, visualization of ectatic, slow-emptying veins, vascular tufts, or early-filling veins establishes the diagnosis.⁸⁸ During endoscopy, angiodysplasias appear as red, flat lesions about 2 to 10 mm in diameter, sometimes accompanied by a feeding vessel.^{4,21}

Typically, the bleeding caused by colonic AVMs is chronic, slow, and intermittent. Although these lesions can cause severe lower GI hemorrhage, they are a relatively uncommon cause. The bleeding stops spontaneously in 85 to 90% of cases,⁸⁸ but it recurs in 25 to 85%.⁸⁹ Accordingly, definitive surgical or colonoscopic treatment should be rendered once the lesion has been identified.

Colonic AVMs are usually amenable to endoscopic treatment. That these lesions are frequently found in the right colon makes perforation a concern; this complication is reported in approximately 2% of patients. Good success rates

have been reported with both injection and thermal methods.⁹⁰ In one series, endoscopic fulguration was successful in 87% of patients, and no rebleeding episodes occurred over a 1- to 7-year follow-up period.⁹⁰ Bleeding from multiple telangiectatic lesions in the distal colon resulting from radiation injury can be treated with thermal contact probes, lasers, or noncontact devices such as the argon plasma coagulator.

NEOPLASIA

Significant GIB from colorectal neoplasia [see 5:15 *Adenocarcinoma of the Colon and Rectum*] accounts for 7 to 33% of cases of severe lower GI hemorrhage.^{3,18} Such bleeding is believed to result from erosions on the luminal surface. Adenomatous polyps are implicated in 5 to 11% of cases of acute LGIB.⁹¹

LGIB, either immediate or delayed, is the most common reported complication after endoscopic polypectomy, occurring in 0.2 to 6% of cases.^{3,84} Immediate postpolypectomy bleeding is believed to result from incomplete coagulation of the stalk before transection. Delayed bleeding has been reported as long as 15 days after polypectomy and is thought to be secondary to sloughing of the coagulum; it is less common than immediate bleeding, occurring in only 0.3% of cases.⁹² Postpolypectomy hemorrhage can often be successfully treated by endoscopic means. Methods used include simple resnaring of the stalk while pressure is maintained⁹²; electrocauterization, with or without epinephrine injection; endoscopic band ligation; and placement of metallic clips.

BENIGN ANORECTAL DISEASE

Hemorrhoids, ulcer or fissure disease, and fistula in ano [see 5:17 *Benign Rectal, Anal, and Perineal Problems*] must not be overlooked as causes of GI hemorrhage: in one review comprising almost 18,000 cases of LGIB, 11% were attributable to anorectal pathology. It is therefore imperative to perform a digital rectal examination and anoscopy in all patients with LGIB. However, identification of a benign anorectal lesion does not eliminate the possibility of a more proximal cause of hemorrhage. Patients with hemorrhoids identified on physical examination should therefore still undergo thorough endoscopic evaluation of the colon to rule out other pathologic conditions. For patients whose bleeding is attributable to benign anorectal causes, endoscopic therapy may include epinephrine injection, sclerosant injection, or band ligation of internal hemorrhoids.⁹³

Portal hypertension [see 5:10 *Portal Hypertension*], congestive heart failure, and splenic vein thrombosis can cause colonic or anorectal varices, which can result in massive lower GI hemorrhage. The reported incidence of anorectal varices in patients with portal hypertension ranges from 78 to 89%.⁹⁴ If local measures fail to control hemorrhage, some form of portosystemic shunting is indicated.

COLITIS

The broad term *colitis* includes IBD, infectious colitis, radiation colitis, and idiopathic ulcers. IBD, in turn, includes Crohn disease [see 5:11 *Crohn Disease*] and ulcerative colitis [see 5:13 *Fulminant Ulcerative Colitis*]. Patients with IBD usually present with bloody diarrhea that is not life-threatening; however, 6 to 10% of patients with ulcerative colitis have

LGIB severe enough to necessitate emergency surgical resection,⁹⁵ and 0.6 to 1.3% of patients with Crohn disease have acute life-threatening LGIB.⁹⁵ In one review, 50% of patients with intestinal hemorrhage from IBD experienced spontaneous cessation of bleeding.⁹⁵ Approximately 35% of patients whose bleeding stops without intervention will have another bleeding episode. Because of this high recurrence rate, semielective surgery is recommended after the first episode of severe GIB secondary to IBD.

Colitis caused by various infectious agents (e.g., typhi, *Escherichia coli* O157:H7, *Clostridium difficile*, and cytomegalovirus) can result in severe LGIB, but this is a relatively rare occurrence.

Increasing use of radiation therapy to treat pelvic malignancies has led to a corresponding increase in the incidence of chronic radiation proctitis. Radiation therapy damages bowel mucosa, resulting in the formation of vascular ectasias that are prone to bleeding. From 1 to 5% of cases of acute LGIB from radiation-induced proctocolitis are severe enough to necessitate hospitalization.⁸⁴ In a survey of patients with prostate cancer who underwent pelvic irradiation, 5% of the patients reported hematochezia daily.⁹⁶ Initial therapy for clinically significant hematochezia related to radiation proctitis should include some form of endoscopic treatment (e.g., argon-beam coagulation). Surgery should be reserved for unstoppable hemorrhage or other major complications, such as fistulas and strictures.

COAGULOPATHY

LGIB can be a presenting symptom for both patients with iatrogenic coagulopathy from heparin or warfarin therapy and patients with a hematologic coagulopathy from thrombocytopenia [see *1:4 Bleeding and Transfusion*]. It is unclear, however, whether severe coagulopathy leads to spontaneous hemorrhage or whether it predisposes to bleeding from an existing lesion.⁹⁷ In an early series of leukemic patients with thrombocytopenia and severe GI hemorrhage, 50% of bleeding patients had platelet counts lower than 20,000/ μ L without any identifiable mucosal lesions; furthermore, when the platelet count rose above 20,000/ μ L, the incidence of bleeding decreased to 0.8%.⁹⁷ The investigator concluded that severe thrombocytopenia led to spontaneous GI hemorrhage. Other investigators subsequently challenged this conclusion, arguing that spontaneous bleeding from coagulopathy is, in fact, rare. In one report, the distribution of pathologic lesions in patients with GIB who were taking heparin or warfarin was essentially equivalent to that in the general population.⁹⁸ Regardless of what the precise relation between coagulopathy and GI hemorrhage may be, a thorough investigation for an anatomic lesion is imperative in the workup of patients with LGIB even in the face of coagulopathy or thrombocytopenia.

COLONIC ISCHEMIA

Acute LGIB can also be a presenting symptom of colonic ischemia. In several large series, colonic ischemia accounted for 3 to 9% of cases of acute lower GI hemorrhage.^{84,91} Other

vascular diseases reported as potential causes are polyarteritis nodosa, Wegener granulomatosis, and rheumatoid vasculitis. The resultant vasculitis can cause ulceration, necrosis, and, ultimately, hemorrhage.

More than 80% of patients with colonic ischemia respond to bowel rest, IV fluids, and antibiotics and do not require surgical intervention.⁹⁹ When exploration is indicated because of peritonitis or recalcitrant disease, all questionable bowel should be resected with stoma creation unless a second-look operation is planned.

SMALL INTESTINAL SOURCES

Small intestinal sources account for 0.7 to 9% of cases of acute LGIB.^{3,84} About 70 to 80% of cases of small bowel hemorrhage are attributable to AVMs; other, less common causes are jejunoileal diverticula, Meckel diverticulum, neoplasia, regional enteritis, and aortoenteric fistulas. Accurate localization of a bleeding site in the small intestine can be highly challenging: the length and the free intraperitoneal position of the small bowel make endoscopic examination difficult, and the nature of the overlying loops makes angiographic localization imprecise. For these reasons, the small intestine is usually left for last in the attempt to localize the source of LGIB and is examined only after sources in the colon, upper GI tract, and anorectum have been ruled out.

AIDS

The etiology of LGIB in patients with AIDS differs from that in the general population. In AIDS patients, LGIB is caused predominantly by conditions related to the underlying HIV infection. Cytomegalovirus colitis is the most common cause of such bleeding in this population, occurring in 39% of cases. AIDS patients with hemorrhoids or anal fissures often experience significant bleeding as a result of HIV-induced thrombocytopenia. A 1998 study reported that in 23% of AIDS patients hospitalized for LGIB, benign anorectal disease was the cause.¹⁰⁰ Other significant causes of lower GI hemorrhage in this population are colonic histoplasmosis, Kaposi sarcoma of the colon, and bacterial colitis.¹⁰⁰

NSAIDS

The association between NSAID use and UGIB is well known. Current data suggest that NSAIDs have a toxic effect on colonic mucosa as well. An epidemiologic study estimated the incidence of NSAID-associated large bowel bleeding to be 7 in 100,000.¹⁰¹ A retrospective review found that patients who had experienced LGIB were twice as likely to have taken NSAIDs as those who had not.¹⁰² NSAIDs have also been linked to diverticular hemorrhage. The exact mechanism of NSAID-induced colonic injury is unknown.

Financial Disclosures: The author is a consultant to Boston Scientific, Terumo, and Ethicon Endosurgery and received an honorarium from Covidien.

6 LOWER GASTROINTESTINAL BLEEDING

Michael J. Rosen, M.D., and Jeffrey L. Ponsky, M.D., F.A.C.S.

Approach to Lower GI Bleeding

Lower gastrointestinal bleeding is defined as abnormal hemorrhage into the lumen of the bowel from a source distal to the ligament of Treitz. In the majority of cases, lower GI bleeding derives from the colon; however, the small bowel is identified as the source of bleeding in as many as one third of cases,^{1,2} and the upper GI tract is identified as the source in as many as 11% of patients presenting with bright-red blood per rectum.³

Lower GI bleeding is more common in men than in women. The incidence rises steeply with advancing age, exhibiting a greater than 200-fold increase from the third decade of life to the ninth. This increase is largely attributable to the various colonic disorders commonly associated with aging (e.g., diverticulosis and angiodysplasia).⁴⁻⁶ The exact incidence of lower GI bleeding is not known, because there is no standardized technique for localizing it. Several investigators, however, estimate the incidence to be in the range of 20 to 27 cases per 100,000 adults.^{4,7} A 1997 survey of GI bleeding from the American College of Gastroenterology found that lower GI hemorrhage accounted for 24% of all GI bleeding events.⁸ Another study published the same year found that 0.7% of 17,941 discharges from a Veterans Affairs hospital were for patients who had had lower GI bleeding.⁹

The basic components of management are (1) initial hemodynamic stabilization, (2) localization of the bleeding site, and (3) site-specific therapeutic intervention. There are many conditions that can cause lower GI hemorrhage [see Discussion, Etiology of Lower GI Bleeding, *below*]; accordingly, successful localization depends on timely and appropriate use of a variety of diagnostic tests. Despite the abundance of diagnostic modalities available, attempts to localize the source of the hemorrhage fail in as many as 8% to 12% of patients.^{10,11} Once the bleeding site is localized, the appropriate therapeutic intervention must be carried out as expeditiously as possible.

Lower GI bleeding can be acute and life-threatening, chronic, or even occult. In what follows, we focus on severe, life-threatening hematochezia, reviewing the wide array of possible causes of lower GI bleeding and outlining the diagnostic and therapeutic modalities available for treating this difficult clinical problem.

Initial Evaluation and Resuscitation

Initial evaluation of a patient with lower GI bleeding should include a focused history and physical examination, to be carried out simultaneously with resuscitation. Of particular importance in taking the history is to ascertain

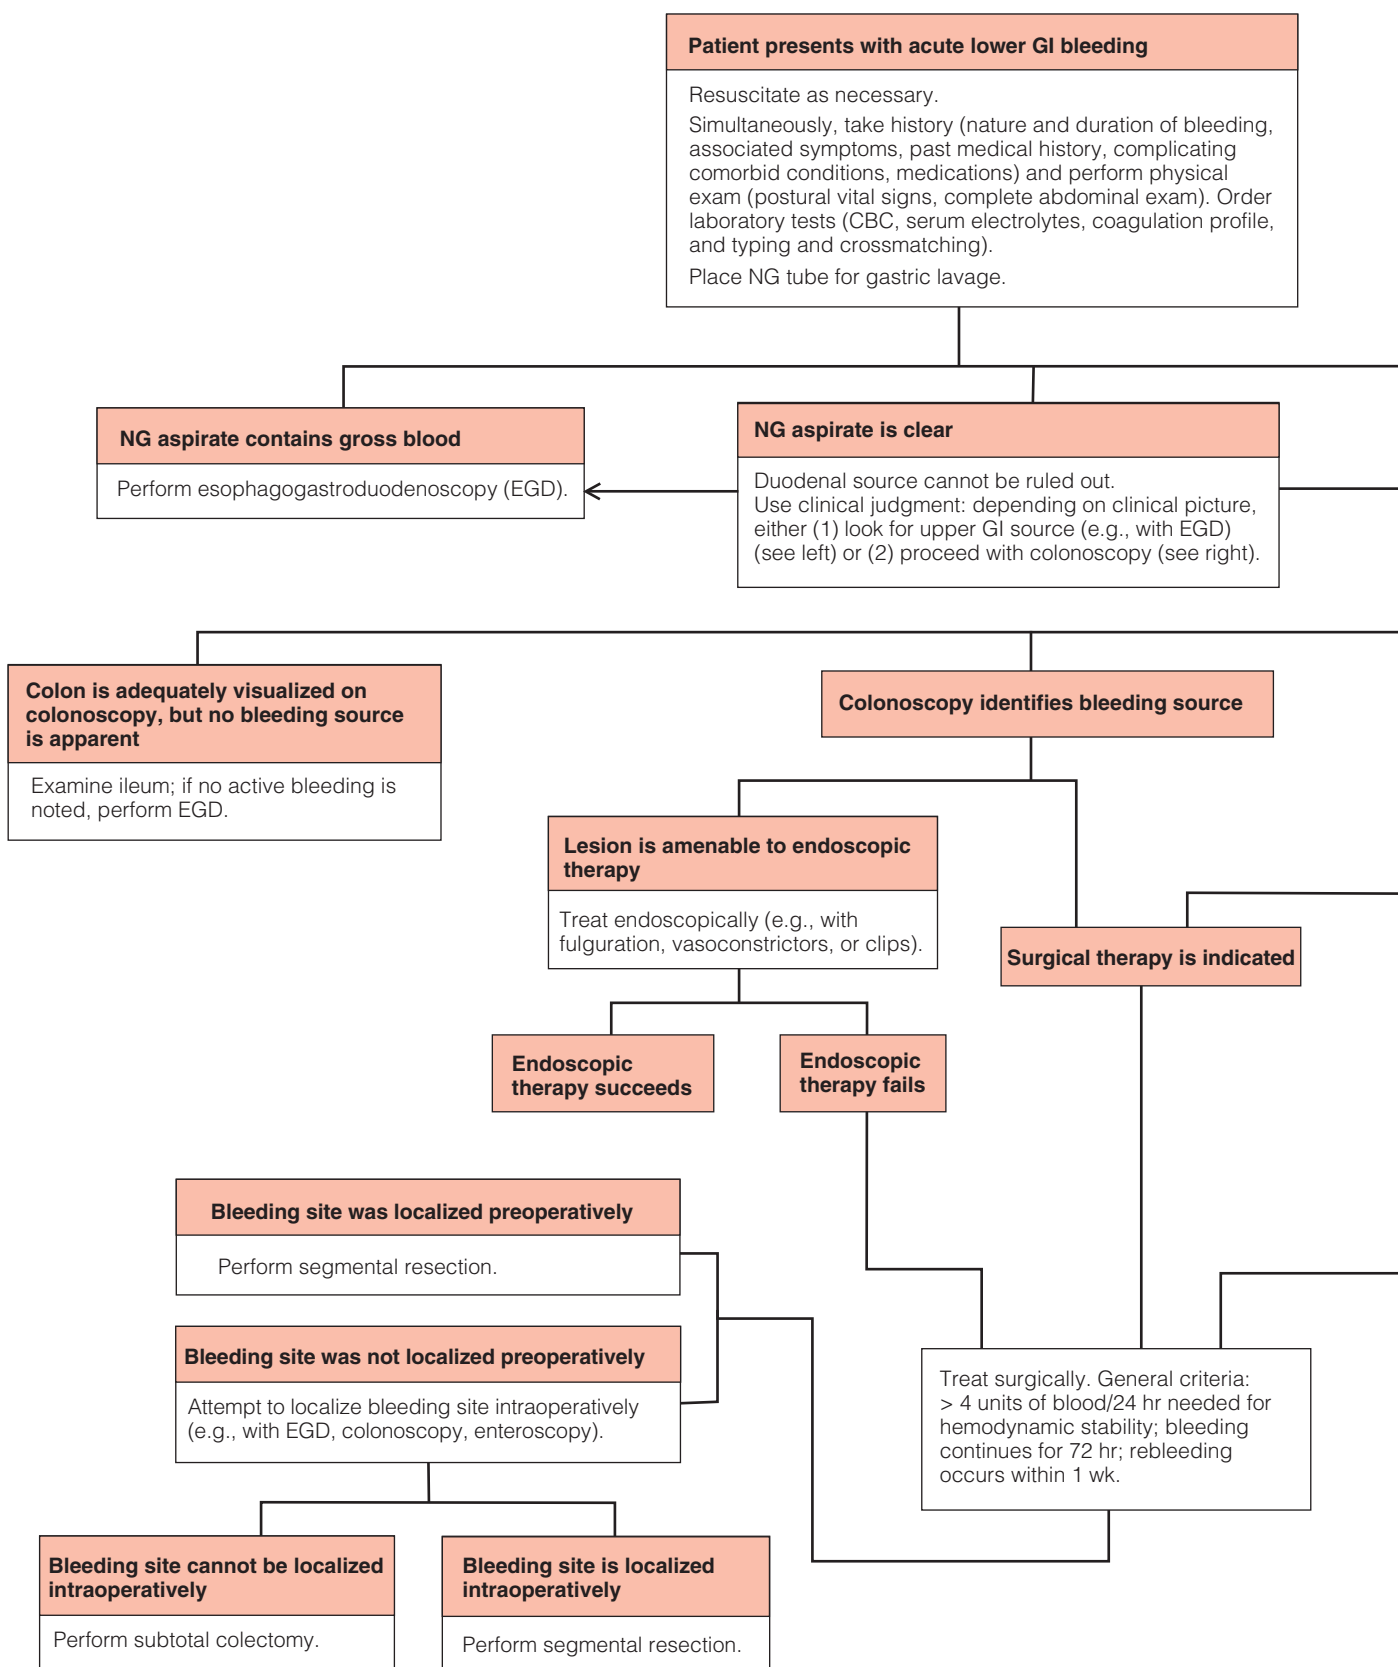

the nature and duration of the bleeding, including stool color and frequency. The patient should also be asked about any associated symptoms of potential significance (e.g., abdominal pain, changes in bowel habits, fever, urgency, tenesmus, or weight loss), as well as about relevant past medical events (e.g., previous GI bleeding episodes, injuries, surgical procedures, peptic ulcer disease, inflammatory bowel disease [IBD], and abdominal or pelvic irradiation). Any complicating comorbid conditions (e.g., heart or liver disease and clotting disorders) should be investigated. A comprehensive review of medications—in particular, nonsteroidal anti-inflammatory drugs (NSAIDs) and anticoagulants—is mandatory.¹²

The physical examination should include determination of postural vital signs so that intravascular volume status can be accurately estimated. A drop in the orthostatic blood pressure greater than 10 mm Hg or an increase in the pulse rate greater than 10 beats/min indicates that more than 800 ml of blood (> 15% of the total circulating blood volume) has been lost. Marked tachycardia and tachypnea in association with hypotension and depressed mental status indicates that more than 1,500 ml of blood (> 30% of the total circulating blood volume) has been lost. A complete abdominal examination, including digital rectal examination and anoscopy, should be performed.

Laboratory evaluation should include a complete blood count, measurement of serum electrolyte concentrations, a coagulation profile (prothrombin time and partial thromboplastin time) [see 1:4 *Bleeding and Transfusion*], and typing and crossmatching.

A nasogastric tube should be placed for gastric lavage. If lavage yields positive results (i.e., the aspirate contains gross blood or so-called coffee grounds), esophagogastroduodenoscopy (EGD) is indicated [see 5:18 *Gastrointestinal Endoscopy*]. An aspirate that contains copious amounts of bile is strongly suggestive of a lower GI source of bleeding, and the workup proceeds accordingly [see Investigative Studies, *below*]. The choice is less clear-cut with a clear aspirate. In the absence of bile, such an aspirate cannot rule out a duodenal source for the bleeding. Accordingly, there is some degree of latitude for clinical judgment: depending on the overall clinical picture, the surgeon may choose either to perform EGD to rule out a duodenal bleeding source or to proceed with colonoscopy on the assumption that the source of the bleeding is in the lower GI tract.

Resuscitative efforts should begin immediately, with the aim of maintaining the patient in a euvolemic state. Two large-bore peripheral intravenous catheters should be inserted and isotonic I.V. fluid administered. A Foley catheter should be placed to facilitate monitoring of intravascular volume status. Whether and in what form to administer blood products is determined on an individual basis, with appropriate weight given to the presence or absence of comorbid conditions, the rate of blood loss, and the

Approach to Lower GI Bleeding

degree of hemodynamic stability. Severe hemodynamic instability may necessitate monitoring in the intensive care unit.

Investigative Studies

A number of diagnostic techniques are available for determining the source of lower GI hemorrhage, the most useful of which are colonoscopy [see 5:18 *Gastrointestinal Endoscopy*], radionuclide scanning, computed tomography, and angiography (in the form of selective mesenteric arteriography). The goal of these tests is to locate the site of bleeding accurately so that definitive therapy can be properly directed. Which diagnostic test is chosen for a specific patient depends on several factors, including the hemodynamic stability of the patient, the bleeding rate, the comorbid conditions present, and the local expertise available at the physician's hospital.

COLONOSCOPY

Several large series that evaluated the diagnostic utility of colonoscopy in patients with lower GI bleeding found this modality to be moderately to highly accurate, with overall diagnostic yields ranging from 53% to 97% [see Table 1].^{3,13-17} Those studies that reported morbidity found colonoscopy to be safe as well, with an average complication rate of 0.5%. Colonoscopy has both a higher diagnostic yield and a lower complication rate than arteriography in this setting and thus would appear to be a more attractive initial test in most circumstances.^{3,18} An argument has been made—one with which we agree—that colonoscopy should be considered the procedure of choice for structural evaluation of lower GI bleeding and that arteriography should be reserved for patients with massive, ongoing bleeding in whom endoscopy is not feasible or colonoscopy fails to reveal the source of the hemorrhage.¹²

The merits of colonic purging have been extensively debated in the literature.^{3,11,14} Although no firm conclusion has been reached, we feel that adequate colonic purging can improve both the diagnostic yield and the safety of colonoscopy. Given the absence of any definitive data suggesting that colonic purging either reactivates or increases bleeding,¹² it is our practice to administer an oral purge after the patient has been adequately resuscitated.

If the entire colon has been adequately visualized and no source for the bleeding has been identified, the ileum should be intubated; fresh blood in this region suggests a possible small bowel source. If no active bleeding is observed in the ileum, upper GI endoscopy should be performed to rule out an upper GI bleeding site.

When colonoscopy and routine upper GI endoscopy fail to locate a bleeding source, push enteroscopy may be helpful. This procedure can be carried out in several ways. It can be performed purely endoscopically with a pediatric colonoscope. This approach generally requires a high level of skill on the part of the endoscopist, in that the lack of retroperitoneal attachments of the small intestine makes endoscopic navigation extremely challenging. In most cases, only the proximal 150 cm of the small intestine can be evaluated in this way. Alternatively, push enteroscopy can be performed in the operating room at the time of exploratory laparotomy. The surgeon can manually “milk” the small bowel over the scope to evaluate its distal portion. In addition, an enterotomy can be made, and the scope can be passed in both a retrograde and an antegrade fashion so that the entire small intestine can be evaluat-

ed. Depending on the indication and on the technique employed, the diagnostic yield from push enteroscopy has ranged from 13% to 78%.¹⁹ Typically, yields are highest (40% to 60%) in patients with significant GI hemorrhage.

RADIOLABELED RED BLOOD CELL SCANNING

Radionuclide scanning is highly sensitive for lower GI hemorrhage: it is capable of detecting bleeding at rates as slow as 0.1 to 0.4 ml/min.²⁰ Two imaging tracers, both labeled with technetium-99m (^{99m}Tc), are currently available for radionuclide scanning in this setting: ^{99m}Tc-labeled sulfur colloid (^{99m}Tc-SC) and ^{99m}Tc-labeled red blood cells (RBCs). ^{99m}Tc-SC requires no preparation time and can be injected immediately into the patient; however, its rapid absorption into the liver and the spleen can often hinder accurate localization of overlying bleeding sites.⁹ At our institution, we prefer to use ^{99m}Tc-labeled RBCs. This agent requires some preparation time, but it has a much longer half-life than ^{99m}Tc-SC does, it is not taken up by the liver and spleen, and it can be detected on images as long as 24 to 48 hours after injection [see Figure 1].^{21,22}

One study directly compared these two techniques and found ^{99m}Tc-labeled RBC scanning to have an accuracy of 93%, compared with an accuracy of only 12% for ^{99m}Tc-SC scanning.²³ The high sensitivity of ^{99m}Tc-labeled RBC scanning—80% to 98%—is well attested, but there is considerable disagreement in the literature with regard to its specificity in identifying the anatomic site of bleeding.²⁴⁻²⁷ For example, on one hand, a 1996 study found radiolabeled RBC scanning to be 97% accurate for localizing bleeding in 37 patients undergoing surgical resection²⁷; on the other hand, a 1990 study reported a 42% rate of incorrect resection when surgical therapy was based solely on this modality.²⁶ In 2005, one group retrospectively reviewed 127 bleeding scans in an effort to identify factors that might predict a positive scan.²⁸ The investigators found that tagged RBC scans were 48% accurate in localizing bleeding sites later confirmed by endoscopy, surgery, or pathologic evaluation. Multivariate analysis demonstrated that both the number of units of blood transfused in the 24 hours preceding the scan and the lowest recorded hematocrit differed significantly between patients with positive scans and those with negative scans. However, the clinical significance of a positive scan was unclear in this study, in that the rate of endoscopy was not significantly different between patients who had positive scans and those who did not.

To date, no prospective, randomized trials have compared radionuclide scanning with colonoscopy as the initial diagnostic procedure for patients with lower GI hemorrhage. In our view,

Table 1 Diagnostic Accuracy of Colonoscopy in Localizing Source of Lower GI Hemorrhage

Study	No. of Patients	Diagnostic Yield (%)
Richter ¹³	78	70 (90%)
Jensen ³	80	68 (85%)
Rossini ¹⁴	409	311 (76%)
Goenka ¹⁵	166	141 (85%)
Ohyama ¹⁶	345	307 (89%)
Chaudhry ¹⁷	85	82 (97%)
Total	1,163	979 (84%)

Figure 1 ^{99m}Tc -labeled RBC scan demonstrates collection of tracer at hepatic flexure.

however, given that radionuclide scanning (unlike colonoscopy and angiography) has no therapeutic intervention capabilities, its best use is in patients with non-life-threatening lower GI bleeding as a prelude and a guide to mesenteric angiography after active hemorrhage has been confirmed.

COMPUTED TOMOGRAPHY

With the ongoing improvements in high-speed abdominal CT scanning, there has been growing interest in the evaluation of GI bleeding with CT.²⁹ Helical CT scanners can provide direct or indirect evidence of the source of GI bleeding. Typical findings that can facilitate localization of bleeding sites include spontaneous hyperdensity of the peribowel fat, contrast enhancement of the bowel wall, vascular extravasation of the contrast medium, thickening of the bowel wall, polyps, tumors, and vascular dilatation.

Figure 2 Angiographic study documents extravasation of contrast into small bowel.

CT evaluation of GI bleeding has several noteworthy advantages: the scanners typically are readily available, mobilization of special teams or units is not required, the scans can be completed rapidly in the emergency department, and bowel preparation is unnecessary. In one experimental study, CT scanners were able to detect arterial bleeding at rates as low as 0.07 ml/min, which suggests that CT scanning is more sensitive than angiography for this purpose.³⁰ In addition, CT scans are noninvasive and carry little morbidity. Unfortunately, like radionuclide scanning, CT has no therapeutic capability.

A 2003 study of 19 patients with GI hemorrhage compared triphasic helical CT evaluation with colonoscopy and surgery for localization of bleeding sites.³⁰ In this series, five patients had small bowel bleeding sites, and 14 had colonic sites. Helical CT scanning correctly identified four of the five small bowel lesions and 11 of the 14 colonic lesions. These findings, though preliminary, suggest that CT is a potentially valuable evaluation method in certain cases of GI bleeding. Perhaps CT scanning can eventually replace radionuclide scanning, which is often inaccurate. One potential drawback to the use of CT in this setting is the excessive dye load if angiography is employed as well.

ANGIOGRAPHY

Selective Mesenteric Arteriography

Selective mesenteric arteriography is somewhat less sensitive than radionuclide scanning for lower GI hemorrhage: bleeding must be occurring at a rate of at least 1.0 to 1.5 ml/min to be detectable with this test.³¹ The procedure involves percutaneous placement of a transfemoral arterial catheter for evaluation of the superior mesenteric, inferior mesenteric, and celiac arteries. A positive test result is defined as extravasation of contrast into the lumen of the bowel [see Figure 2]. Once the bleeding vessel has been localized angiographically, the area must be marked so that it can be successfully identified intraoperatively; this is commonly accomplished by infusing methylene blue into the bleeding artery [see Figure 3].^{32,33}

In several large series [see Table 2], the overall diagnostic yield of arteriography ranged from 27% to 67%.^{27,34-38} The complication rate for arteriography performed for lower GI bleeding ranges from 2% to 4%.^{2,38} Reported complications include contrast allergy, renal failure, bleeding from arterial puncture, and embolism from a dislodged thrombus.¹²

Unlike radionuclide scanning, arteriography provides several therapeutic options, including vasopressin infusion and embolization of bleeding vessels. Nonetheless, given that arteriography has a lower diagnostic yield and a higher complication rate than colonoscopy does, it is reasonable to attempt colonoscopy first in patients with lower GI hemorrhage and to reserve angiography for patients in whom the volume of bleeding is such that colonoscopy would be neither safe nor accurate.

Provocative Angiography for Continued Obscure Bleeding

In a minority of patients, obscure bleeding persists despite negative findings from endoscopy, mesenteric arteriography, and radionuclide RBC scanning. This obscure bleeding presents a considerable diagnostic challenge, which some investigators have proposed addressing by means of so-called provocative angiography.^{39,40}

Figure 3 Intraoperative examination of the bowel is aided by injection of methylene blue dye, which facilitates localization of the bleeding site and thereby helps direct surgical resection.

Provocative angiography involves the use of short-acting anticoagulant agents (unfractionated heparin, vasodilators, thrombolytics, or combinations thereof) in association with angiography. Once the bleeding point has been localized, methylene blue is injected and the patient is immediately brought to the OR for surgical treatment. To date, unfortunately, little has been published on this technique, but it does appear to be a promising approach to this difficult problem.

Management

Although, in the majority of cases, lower GI bleeding stops spontaneously, in a significant number of cases, hemorrhage continues and necessitates therapeutic intervention. Treatment options include endoscopic therapy, angiographic therapy, and surgical resection.

ENDOSCOPIC THERAPY

When colonoscopy identifies a bleeding source, endoscopic treatment may be an option [see 5:18 *Gastrointestinal Endoscopy*]. Endoscopic modalities used to treat lower GI bleeding include use of thermal contact probes,^{41,42} laser photocoagulation,⁴³ electrocauterization,⁴⁴ injection of vasoconstrictors, application of metallic clips,⁴⁵ and injection sclerotherapy.⁴⁶ The choice of a specific modality often depends on the nature of the offending lesion and on the expertise and resources available locally. A 1995 survey of members of the American College of Gastroenterology found that endoscopic therapy was used in 27% of patients presenting with lower GI bleeding.⁸

Diverticular hemorrhage can be difficult to treat endoscopically because of the high bleeding rate and the location of the bleeding point within the diverticulum. In 2000, one group of investigators reported their experience with endoscopic therapy for severe

hematochezia and diverticulosis in a prospective series of 121 patients.⁴⁷ In this series, none of the patients treated endoscopically with epinephrine injections, bipolar coagulation, or both required surgery and none experienced recurrent bleeding episodes. A 2001 study from another group, however, reported high rates of recurrent bleeding episodes in both the early and the late post-treatment periods.⁴⁸ In the absence of prospective, randomized trials, it is difficult to draw definitive conclusions about the utility of endoscopic therapy in treating diverticular hemorrhage.

Angiodysplasias resulting in GI hemorrhage typically are amenable to endoscopic treatment. That these lesions are frequently found in the right colon makes perforation a concern; this complication is reported in approximately 2% of patients.⁴⁹ Good success rates have been reported with both injection and thermal methods.⁵⁰ In one series, endoscopic fulguration was successful in 87% of patients, and no rebleeding episodes occurred over a 1- to 7-year follow-up period.⁵⁰ Bleeding from multiple telangiectatic lesions in the distal colon resulting from radiation injury can be treated with thermal contact probes, lasers, or noncontact devices such as the argon plasma coagulator.⁵¹

Postpolypectomy hemorrhage can often be successfully treated by endoscopic means. Methods used include simple resnaring of the stalk while pressure is maintained⁵²; electrocauterization, with or without epinephrine injection; endoscopic band ligation; and placement of metallic clips. For patients whose bleeding is attributable to benign anorectal causes, endoscopic therapy may include epinephrine injection, sclerosant injection, or band ligation of internal hemorrhoids.⁵³

ANGIOGRAPHIC THERAPY

Diagnostic use of angiography in patients with lower GI bleeding can often be followed by angiographic therapy. The two main angiographic treatment options are intra-arterial injection of vasopressin and transcatheter embolization.

Vasopressin acts to control bleeding by causing arteriolar vasoconstriction and bowel wall contraction.⁹ Once the bleeding site has been localized angiographically, the catheter is positioned in

Table 2 Diagnostic Accuracy of Mesenteric Angiography in Localizing Source of Lower GI Hemorrhage

Study	No. of Patients	No. of Positive Angiograms (%)
Pennoyer ³⁴	131	37 (28%)

Rantis ³⁵	30	8 (27%)
Leitman ³⁶	68	27 (40%)
Casarella ³⁷	69	46 (67%)
Colacchio ³⁸	98	40 (41%)
Total	445	180 (40%)

the main trunk of the vessel. Infusion of vasopressin is initiated at a rate of 0.2 U/min and can be increased to a rate of 0.4 U/min. Within 20 to 30 minutes, another angiogram is performed to determine whether the bleeding has ceased. If the bleeding is under control, the catheter is left in place and vasopressin is continuously infused for 6 to 12 hours. If the bleeding continues to be controlled, infusion is continued for an additional 6 to 12 hours at 50% of the previous rate. Finally, vasopressin infusion is replaced by continuous saline infusion, and if bleeding does not recur, the catheter is removed.^{54,55}

The vasoconstrictive action of vasopressin can have deleterious systemic side effects, including myocardial ischemia, peripheral ischemia, hypertension, dysrhythmias, mesenteric thrombosis, intestinal infarction, and death.^{9,36} Occasionally, simultaneous I.V. administration of nitroglycerin is necessary to counteract these systemic effects. The reported success rate of vasopressin in controlling lower GI bleeding ranges from 60% to 100%, and the incidence of major complications ranges from 10% to 20%.⁵⁶⁻⁵⁸ Rebleeding rates as high as 50% have been reported.^{57,58}

An alternative for patients with coronary vascular disease, severe peripheral vascular disease, or other comorbidities that prevent safe administration of vasopressin is transcatheter embolization. In this technique, a catheter is superselectively placed into the identified bleeding vessel and an embolizing agent (e.g., a gelatin sponge, a microcoil, polyvinyl alcohol particles, or a balloon) is injected. Several small series found this technique to be 90% to 100% successful at stopping bleeding.⁵⁹⁻⁶³ Equally impressive was the finding that the rebleeding rates in these series were 0%. The complication rates of this procedure are generally reasonable as well; however, intestinal infarction has been reported.^{36,64}

The use of small microcatheters and the ability to superselectively embolize individual vessels have reduced the potential for ischemic perforation. It is possible that as more experience is gained with these techniques, superselective embolization may replace catheter-directed vasoconstrictive therapy, thus obviating the potential deleterious systemic effects of vasopressin administration. Some researchers have suggested that with the exception of cases of diffuse bleeding lesions or cases whose demands exceed the technical limitations of superselective catheterization, emboli-

zation therapy should be the first choice for angiographic treatment of lower GI bleeding.^{65,66}

SURGICAL THERAPY

Although there are no absolute criteria for surgical treatment of lower GI bleeding, there are several factors—including hemodynamic status, associated comorbidities, transfusion requirements, and persistent bleeding—that are instrumental in making an appropriate and timely decision whether to operate. In general, patients who require more than 4 units of blood in a 24-hour period to remain hemodynamically stable, whose bleeding has not stopped after 72 hours, or who experience rebleeding within 1 week after an initial episode should undergo surgery.⁹

If the patient's hemodynamic status permits, surgical treatment should be undertaken after accurate localization of the bleeding site. When possible, directed segmental resection is the procedure of choice: it is associated with rebleeding rates ranging from 0% to 14% and mortality rates ranging from 0% to 13%.^{10,36,67} Blind segmental colectomy should never be performed: it is associated with rebleeding rates as high as 75% and mortality rates as high as 50%.⁶⁸ If hemodynamic compromise and ongoing hemorrhage make it necessary to perform surgical exploration before the bleeding site can be localized, every effort should be made to identify the source of bleeding intraoperatively before embarking on resection. Intraoperative options for bleeding-site localization include colonoscopy (to allow for this option, patients should always be placed in the lithotomy position), EGD, and transoral passage of a pediatric colonoscope for enteroscopy with simultaneous intraperitoneal assistance for small bowel manipulation.⁹ If the bleeding site still cannot be accurately localized, subtotal colectomy is the procedure of choice. This procedure is associated with mortality rates ranging from 5% to 33%,^{69,70} which underscores the importance of accurate preoperative localization of bleeding before surgical intervention.

Discussion

Etiology of Lower GI Bleeding

As noted, lower GI bleeding has a wide array of possible causes [see Table 3].^{9,71} Of these, diverticular disease is the most common, accounting for 30% to 40% of all cases.⁷² Arteriovenous malformations (AVMs), though extensively described in the literature, are considerably less common causes, accounting for 1% to 4% of cases.^{73,74} Other significant causative conditions are IBD, benign and malignant neoplasms, ischemia, infectious colitis, anorectal disease, coagulopathy, use of NSAIDs, radiation proctitis, AIDS, and small bowel disorders.

DIVERTICULAR DISEASE

The reported prevalence of colonic diverticulosis in Western societies is 37% to 45%.⁷⁵ The vast majority of colonic diverticula are actually false diverticula (pseudodiverticula) that contain only serosa and mucosa [see 5:12 Diverticulitis]. They occur at weak points in the colonic wall where the vasa recta penetrate the mus-

cularis to supply the mucosa⁹; as the diverticulum expands, these vessels are displaced. A 1976 anatomic study of colonic specimens from patients with diverticular bleeding used angiography to demonstrate that in all cases, the vasa recta overlying the diverticulum ruptured into the lumen of the diverticulum, not into the peritoneum [see Figure 4].⁷⁶

It has been estimated that approximately 17% of patients with colonic diverticulosis experience bleeding, which may range from minor to severe and life-threatening.⁷⁷ As many as 80% to 85% of diverticular hemorrhages stop spontaneously.⁷⁸ In one series, surgery was unlikely to be necessary if fewer than 4 units of packed RBCs were transfused in a 24-hour period, whereas 60% of patients receiving more than 4 units of packed RBCs in a 24-hour period required surgical intervention.⁵ The risk of a second bleeding episode is approximately 25%.³ Semielective surgical therapy is usually offered after a second diverticular bleeding episode because once a second such episode has occurred, the risk that a

Table 3 Common Causes of Lower GI Hemorrhage

Cause of Bleeding	Frequency
Diverticulosis	17%–40%
Arteriovenous malformation	2%–30%
Colitis	9%–21%
Neoplasia (including postpolypectomy bleeding)	7%–33%
Benign anorectal disease	4%–10%
Upper GI source	0%–11%
Small bowel source	2%–9%

third will follow exceeds 50%.⁷⁹ In a series of 83 conservatively managed cases of diverticular disease, the predicted yearly recurrence rates were 9% at 1 year, 10% at 2 years, 19% at 3 years, and 25% at 4 years.⁴

COLITIS

The broad term colitis includes IBD, infectious colitis, radiation colitis, and idiopathic ulcers. IBD, in turn, includes Crohn disease [see 5:11 *Crohn Disease*] and ulcerative colitis [see 5:13 *Fulminant Ulcerative Colitis*]. Patients with IBD usually present with bloody diarrhea that is not life-threatening; however, 6% to 10% of patients with ulcerative colitis have lower GI bleeding severe enough to necessitate emergency surgical resection,^{80,81} and 0.6% to 1.3% of patients with Crohn disease have acute life-threatening lower GI bleeding.^{80,82} In one review, 50% of patients with intestinal hemorrhage from IBD experienced spontaneous cessation of bleeding.⁸⁰ Approximately 35% of patients whose bleeding stops without intervention will have another bleeding episode. Because of this high recurrence rate, semielective surgery is recommended after the first episode of severe GI bleeding secondary to IBD.

Colitis caused by various infectious agents (e.g., *Salmonella typhi*,^{83,84} *Escherichia coli* O157:H7,⁸⁵ *Clostridium difficile*,⁸⁶ and

cytomegalovirus) can result in severe lower GI bleeding, but this is a relatively rare occurrence.

Increasing use of radiation therapy to treat pelvic malignancies has led to a corresponding increase in the incidence of chronic radiation proctitis.⁸⁷ Radiation therapy damages bowel mucosa, resulting in the formation of vascular telangiectases that are prone to bleeding.⁸⁸ From 1% to 5% of cases of acute lower GI bleeding from radiation-induced proctocolitis are severe enough to necessitate hospitalization.^{4,14} In a survey of patients with prostate cancer who underwent pelvic irradiation, 5% of the patients reported hematochezia daily.⁸⁹ Initial therapy for clinically significant hematochezia related to radiation proctitis should include some form of endoscopic treatment (e.g., argon-beam coagulation). Surgery should be reserved for unstoppable hemorrhage or other major complications, such as fistulas and strictures.⁸⁷

NEOPLASIA

Significant GI bleeding from colorectal neoplasia [see 5:15 *Adenocarcinoma of the Colon and Rectum*] accounts for 7% to 33% of cases of severe lower GI hemorrhage.^{3,11,14,36,90} Such bleeding is believed to result from erosions on the luminal surface.⁹¹ One report identified ulcerated cancers as the cause in 21% of cases of hematochezia.¹⁴ Adenomatous polyps are implicated in 5% to 11% of cases of acute lower GI bleeding.^{7,8,14,92,93} Lower GI hemorrhage, either immediate or delayed, is the most common reported complication after endoscopic polypectomy, occurring in 0.2% to 6% of cases.^{3,4,94,95} Immediate postpolypectomy bleeding is believed to result from incomplete coagulation of the stalk before transection.⁵² Delayed bleeding has been reported as long as 15 days after polypectomy and is thought to be secondary to sloughing of the coagulum; it is less common than immediate bleeding, occurring in only 0.3% of cases.^{14,52}

COAGULOPATHY

Lower GI bleeding can be a presenting symptom both for patients with iatrogenic coagulopathy from heparin or warfarin therapy and for patients with a hematologic coagulopathy from thrombocytopenia [see 1:4 *Bleeding and Transfusion*]. It is unclear, however, whether severe coagulopathy leads to spontaneous hemorrhage or whether it predisposes to bleeding from an existing lesion.^{96,97} In an early series of leukemic patients with thrombocytopenia and severe GI hemorrhage, 50% of bleeding patients had platelet counts lower than 20,000/mm³ without any identifiable mucosal lesions; furthermore, when the platelet count rose above 20,000/mm³, the incidence of bleeding decreased to 0.8%.⁹⁶ The investigator concluded that severe thrombocytopenia led to spontaneous GI hemorrhage. Other investigators subsequently challenged this conclusion, arguing that spontaneous bleeding from coagulopathy is in fact rare.⁹⁸ In one report, the distribution of pathologic lesions in patients with GI bleeding who were taking heparin or warfarin was essentially equivalent to that in the general population.⁹⁸ Regardless of what the precise relation between coagulopathy and GI hemorrhage may be, a thorough investigation for an anatomic lesion is imperative in the workup of patients with lower GI bleeding even in the face of coagulopathy or thrombocytopenia.

BENIGN ANORECTAL DISEASE

Hemorrhoids, ulcer/fissure disease, and fistula in ano [see 5:17 *Benign Rectal, Anal, and Perineal Problems*] must not be overlooked as causes of GI hemorrhage: in one review comprising almost 18,000 cases of lower GI bleeding, 11% were attributable to anorectal pathology. It is crucial to remember that identification of

Figure 4 Shown is the appearance of a bleeding diverticulum on colonoscopy.

Figure 5 Shown is the appearance of an arteriovenous malformation on colonoscopy.

a benign anorectal lesion does not eliminate the possibility of a more proximal cause of hemorrhage. In general, patients with hemorrhoids identified on physical examination should still undergo thorough endoscopic evaluation of the colon to rule out other pathologic conditions.

Portal hypertension [see 5:10 Portal Hypertension], congestive heart failure, and splenic vein thrombosis can cause colonic or anorectal varices, which can result in massive lower GI hemorrhage.⁹⁹ The reported incidence of anorectal varices in patients with portal hypertension ranges from 78% to 89%.^{100,101} If local measures fail to control hemorrhage, some form of portosystemic shunting is indicated.

COLONIC ARTERIOVENOUS MALFORMATIONS

The term arteriovenous malformation includes vascular ectasias, angiomas, and angiodysplasias. AVMs are ectatic blood vessels seen in the mucosa and submucosa of the GI tract. They are degenerative lesions of the GI tract, occurring more frequently with advancing age.⁹ In autopsy series, the reported incidence of colonic AVMs is 1% to 2%.¹⁰² In patients older than 50 years, the incidence of colonic AVMs is estimated to range from 2% to 30%.¹⁰³⁻¹⁰⁶ In healthy asymptomatic adults, the prevalence is estimated to be approximately 0.8%.¹⁰⁷

Colonic AVMs are believed to derive from chronic colonic wall muscle contraction, which leads to chronic partial obstruction of the submucosal veins, causing the vessels to become dilated and tortuous. This process eventually renders the precapillary sphincters incompetent, resulting in direct arterial-venous communication.^{108,109} Colonic AVMs are most commonly found in the cecum.¹⁰ They have been associated with several systemic diseases, including atherosclerotic cardiovascular disease, aortic stenosis, chronic renal disease, collagen vascular disease, von Willebrand disease, chronic obstructive pulmonary disease, and cirrhosis of the liver; to date, however, no definite causal relationship to any of these conditions has been established.^{6,21,44,110}

The diagnosis of a colonic AVM is made at the time of angiography or colonoscopy. During angiography, visualization of ectatic, slow-emptying veins, vascular tufts, or early-filling veins estab-

lishes the diagnosis.¹¹¹ During endoscopy, angiodysplasias appear as red, flat lesions about 2 to 10 mm in diameter, sometimes accompanied by a feeding vessel [see Figure 5].^{6,41,44,72}

Typically, the bleeding caused by colonic AVMs is chronic, slow, and intermittent.⁹ Although these lesions can cause severe lower GI hemorrhage, they are a relatively uncommon cause: in most large series, they account for only about 2% of cases of acute bleeding.^{74,104} The bleeding stops spontaneously in 85% to 90% of cases,¹⁰ but it recurs in 25% to 85%.¹¹² Accordingly, definitive surgical or colonoscopic treatment should be rendered once the lesion has been identified.

COLONIC ISCHEMIA

Acute lower GI bleeding can also be a presenting symptom of colonic ischemia. In several large series, colonic ischemia accounted for 3% to 9% of cases of acute lower GI hemorrhage.^{4,7,8,14,92} Other vascular diseases reported as potential causes are polyarteritis nodosa, Wegener granulomatosis, and rheumatoid vasculitis.^{113,114} The resultant vasculitis can cause ulceration, necrosis, and ultimately hemorrhage.¹¹⁵

SMALL INTESTINAL SOURCES

Small intestinal sources account for 0.7% to 9% of cases of acute lower GI bleeding.^{3,4,116-118} About 70% to 80% of cases of small bowel hemorrhage are attributable to AVMs; other, less common causes are jejunoileal diverticula, Meckel's diverticulum,¹¹⁹ neoplasia, regional enteritis, and aortoenteric fistulas [see Figure 6].^{90,120,121}

Figure 6 Shown are intraoperative specimens of small bowel tumors causing lower GI hemorrhage.

Accurate localization of a bleeding site in the small intestine can be highly challenging: the length and the free intraperitoneal position of the small bowel make endoscopic examination difficult, and the nature of the overlying loops makes angiographic localization imprecise. For these reasons, the small intestine is usually left for last in the attempt to localize the source of lower GI bleeding and is examined only after sources in the colon, the upper GI tract, and the anorectum have been ruled out.⁹

AIDS

The etiology of lower GI bleeding in patients with AIDS differs from that in the general population.⁹¹ In AIDS patients, lower GI bleeding is caused predominantly by conditions related to the underlying HIV infection. Cytomegalovirus colitis is the most common cause of such bleeding in this population, occurring in 39% of cases.¹²² AIDS patients with hemorrhoids or anal fissures often experience significant bleeding as a result of HIV-induced thrombocytopenia.¹²² A 1998 study reported that in 23% of AIDS

patients hospitalized for lower GI bleeding, benign anorectal disease was the cause.¹²³ Other significant causes of lower GI hemorrhage in this population are colonic histoplasmosis, Kaposi sarcoma of the colon, and bacterial colitis.^{123,124}

NSAID USE

The association between NSAID use and upper GI hemorrhage is well known.¹²⁵ Current data suggest that NSAIDs have a toxic effect on colonic mucosa as well.¹²⁶ An epidemiologic study estimated the incidence of NSAID-associated large bowel bleeding to be 7/100,000.¹²⁷ A retrospective review found that patients who had experienced lower GI bleeding were twice as likely to have taken NSAIDs as those who had not.¹²⁸ NSAIDs have also been linked to diverticular hemorrhage: in one study, 92% of patients with diverticular bleeding were taking NSAIDs.¹⁰⁷ The exact mechanism of NSAID-induced colonic injury is unknown; nevertheless, heightened clinical awareness of this potential cause of lower GI bleeding is warranted.⁹¹

7 SURGICAL TREATMENT OF MORBID OBESITY

Eric J. DeMaria, MD, FACS, and Christopher J. Myers, MD

It is clear that severe obesity is associated with a significant increase in morbidity¹ and a decreased life expectancy.² Morbid obesity—defined as (a) a body weight that exceeds the ideal body weight by 100 lb or more or (b) a body mass index (BMI) greater than 35 kg/m²—has been shown to have a significant genetic basis.^{3,4} To date, attempts to manage morbid obesity with medical weight reduction programs have met with an unacceptably high incidence of recidivism.⁵ The approach that has had the greatest and longest-lasting success in achieving weight loss is bariatric surgery.

Preoperative Evaluation

Many surgeons are afraid to operate on the morbidly obese patient because they presuppose a marked increase in perioperative morbidity and mortality. It is now possible, however, to stratify the mortality risk for patients undergoing gastric bypass (GBP) by using a scoring system known as the Obesity Surgery Mortality Risk Score (OS-MRS), which includes five independent variables that can be identified preoperatively: (1) BMI greater than or equal to 50 kg/m², (2) male gender, (3) hypertension, (4) pulmonary embolus risk (including previous thrombosis, pulmonary embolus, inferior vena cava [IVC] filter, right-side heart failure, and obesity hypoventilation syndrome [OHS]), and (5) patient age greater than or equal to 45 years. These factors were associated with a greater 90-day mortality in a prospective study of 2,075 patients who underwent GBP at a single institution,⁶ which was the basis for the initial proposal of this scoring system. The OS-MRS was subsequently validated in a multicenter study involving four institutions and 4,431 patients.⁷ With the presence of each variable equal to 1 point, each patient's potential score ranged from 0 to 5. Patients with a score of 0 or 1 had a low mortality risk (group A; mortality, 0.2%); those with a score of 2 or 3 had an intermediate mortality risk (group B; mortality, 1.1%); and those with a score of 4 or 5 had a high mortality risk (group C; mortality, 2.4%). These findings suggest that the OS-MRS is a valuable tool that can be effectively used to stratify risk and facilitate surgical decision making and patient discussion regarding bariatric surgery.

Although the morbidly obese patient is certainly at greater risk, this risk can be markedly reduced by paying careful attention to detail in preoperative and postoperative care. The increased risks encountered in these patients include wound infection, dehiscence, thrombophlebitis, pulmonary embolism (PE), anesthetic calamities, acute postoperative asphyxia in patients with obstructive sleep apnea syndrome (SAS), acute respiratory failure, right ventricular or biventricular cardiac failure, and missed acute catastrophes of the abdomen (e.g.,

anastomotic leakage). The ensuing discussion begins by focusing on issues that the surgeon should carefully consider when operating on an extremely overweight patient.

MORBIDITY ASSOCIATED WITH CENTRAL FAT DEPOSITION

Much has been written about the increased health risks inherent in central (android) fat deposition as compared with peripheral (gynoid) fat deposition. It is thought that in the former, the increased metabolic activity of mesenteric fat is associated with increased metabolism of amino acids to sugar, which leads to hyperglycemia and hyperinsulinism. Hyperinsulinism gives rise to increased sodium absorption and hypertension. Furthermore, central obesity has been linked to hypercholesterolemia. Hence, these patients have a significantly higher incidence of diabetes, hypertension, hypercholesterolemia, and gallstones⁸—which explains the higher mortality of the apple distribution of body fat in comparison with the pear distribution. In the past, fat distribution was measured on the basis of the waist-to-hip ratio; however, computed tomographic scanning has shown that abdominal circumference is a more accurate measurement of central fat distribution.⁹ Morbidly obese women have significantly increased intra-abdominal pressure (IAP), and this increase is associated with stress and urge overflow urinary incontinence.¹⁰ With weight loss comes a significant decrease in bladder pressure and correction of incontinence. IAP, as reflected in bladder pressure, appears to be closely correlated with sagittal abdominal diameter and waist circumference but not with waist-to-hip ratio (many morbidly obese patients have both central and peripheral obesity). The increased IAP associated with central obesity may give rise to other comorbid factors as well, including venous stasis ulcers, OHS [see Respiratory Insufficiency of Obesity, *below*], gastroesophageal reflux, and inguinal and incisional hernias.

RESPIRATORY INSUFFICIENCY OF OBESITY

Obese patients are at risk for respiratory difficulties, which may be present before operation or may be exacerbated by an operation. The term pickwickian syndrome (which derives from *The Posthumous Papers of the Pickwick Club*, by Charles Dickens) was resurrected from the late 1800s to describe a morbidly obese 52-year-old man who fell asleep in a poker game while holding a hand containing a full house.¹¹ He was taken to the hospital by friends who presumed he was ill. The pickwickian syndrome is now known to comprise two pulmonary syndromes associated with morbid obesity: SAS and OHS.¹²

Sleep Apnea Syndrome

SAS is a potentially fatal complication of morbid obesity. A diagnosis of SAS should be suspected when there is a

history of loud snoring, frequent nocturnal awakening with shortness of breath, and daytime somnolence. It is estimated that 2% of middle-aged women and 4% of middle-aged men in the US workforce have SAS, and the incidence is markedly higher in the severely obese.¹³ Patients will often admit to falling asleep while driving and waking up with their car on the road's median strip or bumping its guardrail. It is extremely important that trauma surgeons be aware of the relation between obesity and somnolence should a morbidly obese patient be seen in the emergency department after an automobile accident in which he or she fell asleep at the wheel. Patients with SAS suffer from repeated attacks of upper airway obstruction during sleep. The cause is probably related to a large, fat tongue, as well as to excessive fat deposition in the uvula, pharynx, and hypopharynx. The normal genioglossus reflex is depressed, but this depression may be secondary to the excessive weight of the tongue. These patients are notorious snorers. As a result of inadequate stage IV and rapid eye movement (REM) sleep, they are markedly somnolent during the day.

Patients with SAS are at high risk for acute upper airway obstruction and respiratory arrest when undergoing an operation and general anesthesia. Therefore, any patients with suspected SAS should undergo preoperative polysomnography at a sleep center to confirm the diagnosis. Medications are usually ineffective. Stimulants, such as methylphenidate hydrochloride (Ritalin), should not be used. If a patient has a respiratory disturbance index (RDI) greater than 25—indicating more than 25 apneic or hypopneic episodes per hour of sleep—or has cardiac dysrhythmias in association with apnea, treatment by nocturnal nasal continuous positive airway pressure (nasal CPAP) should be provided. With this technique, air flowing through a nasal mask against a constant airway resistance enters the nasal pharynx and pushes the tongue forward to prevent recurrent obstruction.¹⁴ The pressure can be adjusted for each patient. Unfortunately, many patients cannot tolerate the device, because it is cumbersome and noisy and tends to dry out the upper airway, though dryness can be prevented with an inexpensive room humidifier. If the patient has severe SAS with an RDI greater than 40 and does not respond with elimination of the apneic episodes or cannot tolerate nasal CPAP, a tracheostomy should be considered. An extra-long tracheostomy tube is usually necessary because of the depth of the trachea in the morbidly obese patient.

Obesity Hypoventilation Syndrome

OHS is a condition associated with morbid obesity in which a person suffers from hypoxemia and hypercapnia when breathing room air while awake but resting.¹⁵ Spirometry reveals decreases in forced vital capacity, residual lung volume, expiratory reserve volume, functional residual capacity, and maximum minute volume ventilation, usually without obstruction of airflow [see Figure 1]. The most profound decrease is that in expiratory reserve volume; it is probably secondary to increased IAP and a high-riding diaphragm. Thus, these patients have a restrictive rather than an obstructive pulmonary disease. The decreased expiratory reserve volume implies that many alveolar units are collapsed at end-expiration, which leads to perfusion of unventilated alveoli, or shunting. Patients with OHS often are heavy smokers

or have additional pulmonary problems, such as asthma, sarcoidosis, idiopathic pulmonary fibrosis, or recurrent PE. One study of patients who underwent operation for morbid obesity showed no statistically significant difference in weight between those who had OHS and those who did not.¹²

Chronic, severe hypoxemia is associated with three complications that put patients with OHS at risk: polycythemia, pulmonary arterial vasoconstriction, and pulmonary hypertension. The polycythemia further increases the already significant risk of venous thrombosis and PE. If the hemoglobin (Hb) concentration is 16 g/dl or greater, phlebotomy to a concentration of 15 g/dl should be performed to reduce the postoperative risk of venous thrombosis. If the pulmonary arterial pressure (PAP) is 40 mm Hg or higher, consideration should be given to prophylactic insertion of an IVC filter because of the high risk of a fatal pulmonary embolism in these patients.¹⁶ Placement of an IVC filter can be a challenge because the appropriate landmarks cannot be identified in the operating room with fluoroscopy. It is necessary, before operation, to tape a quarter to the patient's back over the second lumbar vertebra with the aid of fixed radiographs and then, during operation, to aim for the quarter with the insertion catheter, using fluoroscopy. Because these patients are usually too heavy for angiography tables, the filter usually cannot be inserted percutaneously in the radiology department.

Chronic hypoxemia also leads to pulmonary arterial vasoconstriction and severe pulmonary hypertension and eventually to right-side heart failure or cor pulmonale with neck vein distention, tricuspid valvular insufficiency, right upper quadrant tenderness secondary to acute hepatic engorgement, and massive peripheral edema.^{17,18} Such patients may also have a significantly elevated pulmonary artery wedge pressure (PAWP), which suggests left ventricular dysfunction.¹⁷ Morbidly obese patients with a history of pulmonary disease or a BMI greater than 50 kg/m² should have preoperative determinations of blood gas values. If arterial blood gas (ABG) measurement reveals severe hypoxemia (i.e., arterial oxygen tension [P_{aO_2}] ≤ 55 mm Hg), severe hypercapnia (arterial carbon dioxide tension [P_{aCO_2}] ≥ 47 mm Hg), or both, the patient should undergo Swan-Ganz catheterization. If the PAWP is 18 mm Hg or greater, intravenous furosemide should be administered for diuresis before elective operation. However, some patients may require a high ventricular filling pressure. A low cardiac output and hypotension may follow diuresis, necessitating volume reexpansion.

It is highly probable that some of the elevated PAP and PAWP measurements are caused by the increased IAP in the morbidly obese patient [see Figure 2].^{19,20} The high IAP leads to an elevated diaphragm, which in turn increases intrapleural pressure and thereby PAP and PAWP; if the pleural pressure is measured with an esophageal transducer, the transmycardial pressure can be estimated. For this reason, these patients may require a markedly elevated PAWP to maintain an adequate cardiac output, and excessive diuresis may lead to hypotension. The same reasoning may be applied to a patient with a distended abdomen resulting from peritonitis and pancreatitis in whom what seem to be unusually high cardiac filling pressures are necessary. Therefore, one must rely on relative changes in cardiac output in response to either

Figure 1 Impaired pulmonary function in the morbidly obese improved significantly after weight loss induced by gastric operation.¹² ERV = expiratory reserve volume; FEV₁ = forced expiratory volume in one second; FRC = functional residual capacity; FVC = forced vital capacity; MVV = maximal voluntary ventilation; TLC = total lung capacity.

volume challenge or diuresis to determine the optimal PAWP in morbidly obese patients.

Patients with OHS respond rapidly to supplemental oxygen. However, oxygen administration is occasionally associated with significant CO₂ retention, which necessitates intubation and mechanical ventilation. Because their pulmonary disease is restrictive rather than obstructive, these patients are usually easy to ventilate without high peak airway pressures. ABG measurements need not return to normal values before extubation; it is only necessary that they return to their preoperative values. These values are achieved early after laparoscopic procedures and, on average, 4 days after major

open upper abdominal operations, when patients experience a decrease in incisional pain.²¹

It is important to emphasize that morbidly obese patients, especially those with respiratory insufficiency, should be placed in the reverse Trendelenburg position to maximize diaphragmatic excursion and to increase residual lung volume.²² These patients will often complain of air hunger and respiratory distress when they lie supine. So-called breaking of the bed at the waist may exacerbate the problem by pushing the abdominal contents into the chest, thereby raising the diaphragm and further reducing lung volumes. Placing these patients in the leg-down position may predispose them to venous stasis, phlebitis, and PE; this tendency should be offset with intermittent venous compression boots [see Thrombophlebitis, Venous Stasis Ulcers, and Pulmonary Embolism, below].²³

Both SAS and OHS can be completely corrected with weight reduction after gastric operation for morbid obesity: the nocturnal apneas resolve, the P_aO₂ rises, and the P_aCO₂ falls to normal as lung volumes improve.¹²

CARDIAC DYSFUNCTION

Morbidly obese patients are at significant risk for coronary artery disease as a result of an increased incidence of systemic hypertension, hypercholesterolemia, and diabetes. Because of this increased risk for cardiac dysfunction, preoperative electrocardiography should be performed on all obese patients 30 years of age or older.

Cardiac dysfunction in the morbidly obese patient is usually associated with respiratory insufficiency of obesity, especially OHS.¹¹ An elevated PAP in these patients may be secondary to hypoxemia-induced pulmonary arterial vasoconstriction, to elevated left atrial pressures secondary to left ventricular dysfunction, or to a combination of these; it may also be secondary to the increased pleural pressures arising from an elevated diaphragm secondary to increased IAP.^{17,20,23} It is unusual for morbidly obese patients without respiratory

Figure 2 In a porcine model, raising intra-abdominal pressure (IAP) caused cardiac index to fall and pulmonary artery wedge pressure (PAWP) to rise. At an IAP of 25 mm Hg, saline was given to restore intravascular volume; cardiac index returned to baseline levels, but PAWP remained elevated.²⁰

insufficiency to experience significant cardiac dysfunction in the absence of severe coronary artery disease. Morbidly obese patients often have systemic hypertension, which can aggravate left ventricular dysfunction; however, mild left ventricular dysfunction can be documented in many morbidly obese patients in the absence of systemic hypertension.^{24,25} Circulating blood volume, plasma volume, and cardiac output increase in proportion to body weight.²⁵ Massively obese patients may occasionally present with acute heart failure: it is reasonable to assume that the enormous metabolic requirements of such patients can present a greater demand for blood flow than the heart can provide. Vigorous diuresis often corrects such acute heart failure. Significant weight loss corrects pulmonary hypertension [see Figure 3], as well as the left ventricular dysfunction associated with respiratory insufficiency.^{17,26}

THROMBOPHLEBITIS, VENOUS STASIS ULCERS, AND PULMONARY EMBOLISM

Morbidly obese individuals have difficulty walking, tend to be sedentary, have a large amount of abdominal weight resting on their IVC, and have increased intrapleural pressure (which impedes venous return).^{18,20} All of these conditions increase the tendency toward phlebothrombosis. Patients are most at risk when immobilized in the supine position for long periods in the OR. These patients have been shown to have low levels of antithrombin, which may increase their tendency toward venous thrombosis.²⁷ It has also been suggested that starvation, particularly in the postoperative period, may be associated with high levels of free fatty acids, which may predispose to perioperative thrombotic complications.²⁸ Patients with severe OHS often have a noticeably elevated PAP, which can lead to right-side heart failure and can increase the risk of venous stasis and thrombosis. Investigators have noted that patients with primary idiopathic pulmonary hypertension are at significant risk for fatal PE.¹³

The risk of deep vein thrombosis (DVT) increases with a prolonged operation or a postoperative period of immobilization, and it increases even further in the morbidly obese patient. Standard or low-molecular-weight heparin should be administered subcutaneously 30 minutes before operation

and at appropriate intervals thereafter (depending on the type of heparin used) for at least 2 days or until the patient is ambulatory. Because respiratory function in the morbidly obese patient is greatly enhanced with the reverse Trendelenburg position, intermittent sequential venous compression boots should be used to counteract the increased venous stasis and the propensity for clotting. It is important that the intermittent venous compression boots be used before induction of anesthesia and throughout the operative procedure. Such boots are usually part of a standard preoperative protocol in gastric procedures for weight control; their use should not be unintentionally neglected in preparation for other elective or emergency procedures on morbidly obese patients. Patients with severe venous stasis disease (e.g., pretibial stasis ulcers or bronze edema) are at significantly increased risk for fatal PE.²⁹ Prophylactic insertion of an IVC filter should be considered in these patients (as for patients with OHS and a high PAP). All patients should make every attempt to walk during the evening after operation. Bariatric surgery-induced weight loss will correct the venous stasis disease in most cases.²⁹

Venous stasis ulcers can be quite difficult to treat in a thin person; they are almost impossible to cure in a patient with morbid obesity [see Figure 4]. The most important goal in the management of these ulcers is weight loss, which almost invariably leads to healing of the ulcer, probably as a result of decreased IAP.²⁹

GALLSTONES

Approximately one third of morbidly obese patients either have had a cholecystectomy or may have had gallstones noted at the time of another intra-abdominal operative procedure (e.g., a gastric operation for morbid obesity). Preoperative evaluation of the gallbladder may be technically quite difficult in morbidly obese patients because ultrasonography may fail to visualize gallstones. Intraoperative ultrasonography is probably much more accurate. Should symptomatic gallstones be present in a patient undergoing a gastric procedure for obesity, the gallbladder should be removed if the surgeon judges it safe to perform this additional procedure. If

Figure 3 Mean pulmonary arterial pressure was significantly improved in 18 patients 3 to 9 months after gastric surgery-induced weight loss of $42\% \pm 19\%$ of excess weight.

Figure 4 This chronic venous stasis ulcer was present for several years in a morbidly obese patient. Healing followed weight loss induced by a gastric operation.

placement of an adjustable gastric band is contemplated, the cholecystectomy should be undertaken first and the indwelling device placed only in the absence of intra-abdominal bile spillage during the procedure.

In past studies, rapid weight loss led to the development of gallstones in 25 to 40% of patients who underwent GBP. The risk of cholelithiasis in this setting can be reduced to 2% by administering ursodeoxycholic acid, 300 mg orally twice daily.³⁰ Laparoscopic cholecystectomy at the time of laparoscopic gastric bypass can be technically challenging; consequently, many surgeons prefer to take an expectant approach to the gallbladder rather than complicate the bariatric procedure with a simultaneous cholecystectomy (unless cholecystectomy is clearly indicated in a particular patient).

PSEUDOTUMOR CEREBRI

Pseudotumor cerebri is an unusual complication of morbid obesity that is associated with benign intracranial hypertension, papilledema, blurred vision, headache, and elevated cerebrospinal fluid pressures.³¹ It has been our experience that patients with pseudotumor cerebri are not at any additional perioperative risk and that CSF need not be removed before anesthesia and major abdominal operations. There is some theoretical concern that gastrointestinal contamination during GBP may cause shunt infection in patients who have been previously treated with indwelling shunts to relieve elevated CSF pressures. Successful weight reduction cures pseudotumor cerebri.^{32,33}

DEGENERATIVE OSTEOARTHRITIS

Degenerative osteoarthritis of the knees, hips, and back is a common complication of morbid obesity. Weight reduction alone may greatly reduce the pain and immobility that afflict these patients. In some cases, the damage may be so extensive that a total joint replacement is desirable; however, joint replacement in patients who weigh more than 250 lb is associated with an unacceptable incidence of loosening.³⁴ Weight reduction by means of a gastric bariatric operation may be the most sensible initial approach, to be followed by joint replacement after weight loss if pain and dysfunction persist.

Operative Planning

ANESTHESIA IN PATIENTS WITH RESPIRATORY INSUFFICIENCY

Morbidly obese patients can be intimidating to the anesthesiologist because they are at significant risk for complications from anesthesia, especially during induction. The risk is particularly great for obese patients with respiratory insufficiency. An obese patient often has a short, fat neck and a heavy chest wall, which make intubation and ventilation a challenge. If endotracheal intubation proves difficult, however, such a patient can usually be well ventilated with a mask. Awake intubation can be performed, with or without fiberoptic aids, but is quite unpleasant and rarely necessary.

It is extremely important that at least two anesthesia personnel be present during induction and intubation for patients with respiratory insufficiency of obesity. An oral airway is inserted after muscle paralysis with succinylcholine

and sodium pentobarbital induction. One person elevates the jaw, hyperextends the neck, and ensures a tight fit of the mask, using both hands. To ensure adequate oxygen delivery, a second person compresses the ventilation reservoir bag, using two hands because of the resistance to air flow from the poorly compliant, heavy chest wall. After ventilation with 100% oxygen for several minutes, intubation is attempted. If difficulties are encountered within 30 seconds, the steps above should be repeated until the patient has been successfully intubated. A volume ventilator is required during operation. Placing the patient in the reverse Trendelenburg position expands total lung volume and facilitates ventilation²²; however, the reverse Trendelenburg position increases lower-extremity venous pressure and therefore mandates the use of intermittent sequential venous compression boots. It is helpful to monitor blood gases through a radial arterial line or a digital pulse oximeter.

LAPAROSCOPIC VERSUS OPEN APPROACH TO BARIATRIC SURGERY

Bariatric surgical procedures, like most other general surgical procedures, have undergone a transition from an open approach to one that places more emphasis on minimally invasive or laparoscopic techniques. Laparoscopic GBP was first described in 1994 and became widely accepted in 1999, though it was not until 2004 that, according to a national audit of bariatric surgery performed at academic centers, the number of laparoscopic GBP procedures performed exceeded the number of open GBP procedures.

At present, the laparoscopic approach to GBP is favored because it achieves a comparable degree of weight loss while possessing some notable advantages over its open counterpart.²¹ Open GBP is performed through an upper midline incision, whereas laparoscopic GBP is performed through five or six small incisions. Abdominal wall retractors and mechanical retraction of the abdominal viscera, which are necessary for adequate exposure during an open procedure, are not required during a laparoscopic procedure, which makes use of gas insufflation (for pneumoperitoneum) and the effects of body positioning and gravity to facilitate intraoperative exposure. With the elimination of the large surgical incision and mechanical retraction, the laparoscopic GBP patient experiences less operative trauma, less postoperative pain, and fewer wound-related complications. In addition, laparoscopic GBP yields less impairment of immediate postoperative pulmonary function and a lower systemic stress response. A 2007 study of 22,422 patients who underwent Roux-en-Y GBP for treatment of morbid obesity compared the outcomes of laparoscopic procedures ($n=16,357$) with those of open procedures ($n=6,065$).³⁵ The mean length of hospital stay was significantly lower in the laparoscopic group (2.7 days versus 4.0 days), as were the overall complication rate (7.4% versus 13.0%), the 30-day readmission rate (2.6% versus 4.7%), the in-hospital mortality (0.1% versus 0.3%), and the mean cost (\$13,743 versus \$14,585 [US]).

CHOICE OF SURGICAL PROCEDURE

The gastric operations performed for morbid obesity include both GBP procedures and gastric restrictive procedures (i.e., gastropasty and gastric banding). Randomized, prospective trials have conclusively shown that GBP is as

effective for weight control as the malabsorptive jejunioileal (JI) bypass is, while resulting in significantly fewer complications.^{36,37} JI bypass is associated with a substantial incidence of both early complications (e.g., acute cirrhosis, electrolyte imbalance, and fulminant diarrhea)³⁸ and late complications (e.g., cirrhosis, interstitial nephritis, arthritis, enteritis, nephrocalcinosis, and recurrent oxalate renal stones).³⁹ If evidence of cirrhosis, renal failure secondary to interstitial nephritis, or other complications mandates reversal of a JI bypass, the patient, if not extremely ill, should be converted to a GBP; otherwise, all the lost weight is sure to be regained, and the obesity-related comorbidity will return. Admittedly, however, some patients have done well after JI bypass and do not need to have the operation reversed.

Several randomized, prospective trials have found that horizontal gastroplasty yields poorer results than GBP.⁴⁰⁻⁴² Failure of horizontal gastroplasty has generally been attributed to technical causes (e.g., enlargement of the proximal pouch or the stoma or disruption of the staple line). Vertical banded gastroplasty (VBG) was developed in the hope that it would solve these technical problems and yield weight loss comparable to that seen after GBP without incurring the significant risk of iron, calcium, and vitamin B₁₂ deficiencies associated with GBP. In the 1990s, a procedure known as adjustable silicone gastric banding was developed, which involved placement of a restrictive ring around the proximal stomach to create a small gastric pouch. In this restrictive procedure, which can be done laparoscopically in the vast majority of patients, weight loss can be enhanced and vomiting minimized by adjusting the ring diameter via transcutaneous access to the subcutaneous reservoir.

Although VBG and, presumably, other restrictive procedures appear to be excellent from a technical point of view,⁴³ multiple randomized, prospective trials have found such approaches to be significantly less effective than standard GBP. In one comparison trial, patients addicted to sweets lost much more weight after GBP than after VBG because they experienced symptoms of dumping syndrome when ingesting sweets.⁴⁴ The failure rate was high after VBG because these patients experienced no difficulties when eating candy or drinking nondietetic sodas. Subsequent randomized, prospective trials confirmed the superiority of GBP.^{45,46} Furthermore, maintenance of successful weight loss after GBP appears to continue for as long as 14 years after operation: in the average patient, weight loss amounts to about two-thirds of excess weight at 1 to 3 years after operation, three-fifths at 5 years, and more than half in years 5 through 10.^{47,48} It has been suggested that standard (i.e., proximal) GBP will fail in 10 to 15% of patients because these patients will frequently nibble on high-fat snacks (e.g., corn chips, potato chips, and buttered popcorn). Such patients may have to be converted to a combined restrictive and malabsorptive procedure, such as partial biliopancreatic diversion (BPD).⁴⁹

The original BPD procedure involves hemigastrectomy and anastomosis of the distal 250 cm of intestine to the stomach; the bypassed small intestine is reanastomosed to the ileum 50 cm from the ileocecal valve. BPD with duodenal switch is a variant of the original procedure in which a linear gastric tube based on the lesser curvature is created (sleeve gastrectomy), with the pylorus left intact, and an ileal Roux limb is brought up for anastomosis to the proximal duodenum. BPD

has been associated with a high incidence of deficiencies of fat-soluble vitamins, hypocalcemia-induced osteoporosis, and protein-calorie malnutrition.⁵⁰ These nutritional deficiencies may be more common in the United States, where fat intake is high, than in many other countries. In Italy, for example, starch intake (as in pasta) probably outstrips fat intake; still, a number of Italian patients have had to be readmitted for parenteral nutrition and extension of the common absorptive intestinal tract because of refractory malnutrition. In some patients, it might be possible to convert a failed proximal GBP into a modified BPD with a 150 cm absorptive ileal limb (a procedure often referred to as distal GBP); however, these patients must also be monitored carefully for deficiencies of fat-soluble vitamins, for osteoporosis, and for malnutrition.

Superobese patients—defined as those whose weight is 225% of ideal body weight or greater or whose body mass index (BMI) is 50 kg/m² or higher—will lose, on average, only about half of their excess weight, rather than two-thirds, after standard GBP. In these patients, a 150 cm proximal Roux-en-Y procedure (so-called long-limb GBP [see Open Proximal Gastric Bypass, Operative Technique, below]) may increase weight loss in the first few years after operation without causing an increase in nutritional complications.⁵¹

In choosing the appropriate surgical approach, it is important to take into account the tremendous surgical revolution that laparoscopy has brought about in the treatment of morbid obesity. Now that every operation performed to treat obesity can be done laparoscopically, laparoscopic bariatric surgery is not only common but, in many centers, predominant. For this reason, as well as because laparoscopic obesity treatment requires advanced technical skills, minimally invasive bariatric procedures have become a cornerstone of training for surgeons now learning laparoscopic surgery.

Vertical Banded Gastroplasty

OPERATIVE TECHNIQUE

The first step in VBG is to make a circular stapled opening in the stomach 5 cm from the esophagogastric junction. A 90 mm bariatric stapler with four parallel rows of staples is then applied once between this opening and the angle of His. (At this point, according to Mason, the originator of the procedure, the volume of the pouch should be measured by means of an Ewald tube placed by the anesthetist; ideally, pouch volume should be 15 mL.)

Next, a strip of polypropylene mesh is wrapped around the gastrogastic outlet on the lesser curvature and sutured to itself—but not to the stomach—in such a way as to create an outlet with a circumference of 5 cm for the small upper gastric pouch [see Figure 5a]. Some surgeons have used a stomal outlet 4.5 cm in circumference, but this smaller outlet has not led to better weight loss; in fact, many patients with the 4.5 cm outlet exhibit maladaptive eating behavior, drinking high-calorie liquids because meat tends to get caught in the small stoma.

Silastic ring gastroplasty [see Figure 5b] is a variant of VBG that uses a vertical staple line and a stoma reinforced with Silastic tubing.

Figure 5 Vertical banded gastroplasty (VBG). Depicted are (a) standard VBG and (b) Silastic ring gastroplasty, a variant of VBG in which the stoma is reinforced with a Silastic tube.

COMPLICATIONS

Complications of VBG include erosion of the polypropylene mesh used to restrict the gastroplasty stoma into the gastric lumen, enlargement of the pouch, stomal stenosis, reflux esophagitis, and mild vitamin deficiencies.⁵² To date, mesh erosion has been infrequently observed after VBG. Pouch enlargement is fairly common with horizontal gastroplasty but is much less likely to occur with VBG, in which the vertical staple line is placed in the thicker, more muscular part of the stomach. In addition, stomal diameter remains fixed with the mesh band. If mesh erosion, pouch enlargement, stomal stenosis, disabling GI reflux, or recurrent vomiting occurs, it is probably best to convert the patient to GBP. In particular, patients with a Silastic ring VBG may exhibit intractable vomiting of solid foods with no evidence of mechanical obstruction. In our experience, conversion of these patients to GBP yields good results and eliminates the vomiting problem. Finally, vitamin deficiencies can usually be prevented by having VBG patients take a standard multivitamin daily for life.

Figure 6 Laparoscopic adjustable gastric banding. Shown is the adjustable gastric banding device used in the procedure.

Laparoscopic Adjustable Gastric Banding

Gastric banding is another form of gastroplasty, in which a synthetic band is placed around the stomach just below the esophagogastric junction. In several series, gastric banding has yielded markedly variable results with respect to achievement of weight loss. Furthermore, it has been associated with slipping or kinking of the banded stoma, obstruction at the band, and intractable vomiting.

Laparoscopic adjustable gastric banding (LAGB) is significant advance over open gastric banding procedures, primarily because of the adjustability of the band. Open gastric banding procedures have used a variety of materials to constrict the gastric lumen and carry a recognized risk of postoperative nausea and vomiting that do not respond to any treatment short of reoperation. The adjustable gastric bands available for use in LAGB [see Figure 6] are silicone devices with an inflatable reservoir that can be inflated or deflated postoperatively through a subcutaneous port placed deep in the abdominal wall for percutaneous access. Saline is injected into or withdrawn from the reservoir to adjust gastric luminal diameter. These diameter changes can be measured by means of barium contrast evaluation, but currently, most adjustments are made without x-ray guidance. If intractable vomiting develops, saline can be removed from the band to alleviate the problem; similarly, if the patient fails to lose weight after operation, additional saline may be injected into the band to narrow the gastric lumen further.

Use of the laparoscopically placed adjustable gastric band (Lap-Band, Allergan Corp., Irvine, CA) was approved by the US Food and Drug Administration in June 2001. Key data on safety and effectiveness were provided by a prospective, single-arm trial involving 299 patients at eight centers in the United States. In this study, patients who completed 36 months of follow-up achieved a mean reduction in BMI of 39% and a mean overall loss of 18% of baseline body weight. However, 28% of patients lost less than 10% of their initial

body weight (a clear definition of failed weight loss). More than half (62%) of these patients lost more than 25% of their excess weight. Most patients (76%) experienced at least one adverse event, and 33% of patients required removal of the banding system.

Subsequent studies have yielded similar results. A 2007 review of two multicenter prospective, single-arm surgical trials evaluating a total of 485 patients who underwent placement of a gastric band (92% laparoscopically) between June 1995 and June 2001 suggested that the procedure was as effective as was previously believed.⁵³ The change in mean BMI (kg/m²) was 38 to 47% at 1 year and 39% at 3 years. The percentage of initial body weight lost was 17 to 18% at 1 year and 18% at 3 years. Similarly, most patients (66 to 76%) experienced upper GI symptoms at 1 year. In one of the trials, 33% of the patients (96/292 patients) had had their bands removed at 9 years, either because of complications or because of inadequate weight loss.⁵³

In a 2006 study comparing outcomes, LAGB proved to be just as safe as, cheaper than, and almost as effective as laparoscopic Roux-en-Y gastric bypass (LRYGB).⁵⁴ This retrospective review of 590 bariatric procedures (120 LRYGB, 470 LAGB) performed between November 2000 and July 2004 suggested that both operating time and duration of hospitalization were significantly shorter in LAGB patients. Complication rates and reoperation rates were similar in the two groups. Patients who underwent LRYGB initially lost weight more rapidly: their mean percentage of excess body weight lost (%EBWL) was 65% during postoperative year 1, compared with 39% for LAGB patients. Thereafter, weight loss slowed, remaining nearly unchanged at 3 years (63%). Patients who underwent LAGB initially lost weight more slowly, but the ongoing weight loss was continuous, eventually approaching that of LRYGB. At 3 years, the %EBWL for LAGB patients was 55%.

OPERATIVE TECHNIQUE

LAGB is performed by using a five-port technique. Initial abdominal access is obtained via a supraumbilical trocar, and the remaining ports are placed sequentially along the right and left costal margins. The liver is retracted via the subxiphoid port, and the proximal stomach is visualized with a laparoscope inserted through the umbilical port.

Subsequent steps are done according to the pars flaccida technique. A retrogastric tunnel for band insertion is created at the posterior confluence of the diaphragmatic crura in a plane of dissection that is easily developed with minimal blunt dissection after electrocauterization of the peritoneal membrane. This tunnel is placed cephalad to the posterior peritoneal reflection, so that the free space of the lesser sac posterior to the stomach is not entered. Additional dissection is then carried out laterally at the angle of His to open the peritoneum and start clearing a plane behind the proximal stomach.

A specially designed implement is inserted behind the stomach from the lesser curvature to the angle of His and used to grasp the tubing of the banding device and pull it around the stomach. The banding device is then locked into place at the chosen location on the proximal stomach [see Figure 7]. Gastrogastric sutures are placed to create a tunnel of stomach overlying the banding device—but not the

Figure 7 Laparoscopic adjustable gastric banding. Once in the correct position on the proximal stomach, the adjustable band is locked into place.

buckle—so as to hold the device in position. The band tubing is brought through the left midclavicular trocar port, which is placed via the left midclavicular line subcostal trocar incision and fixed to the abdominal wall fascia with sutures. The tubing is connected to the reservoir, which is filled with saline.

TROUBLESHOOTING

It is essential to place the band properly during the initial procedure. The results to date suggest that the proximal pouch must be very small to optimize weight loss. In addition, proper placement minimizes—though it does not eliminate—the risk of band slippage and the complications thereof.

Several techniques have been suggested for posterior fixation of the band, but they are more difficult than anterior fixation techniques. With the pars flaccida technique, posterior fixation of the band is not necessary to prevent band slippage. Anterior fixation, however, is routinely performed, with interrupted sutures of nonabsorbable material placed between the distal and the proximal stomach to allow tissue to be apposed over the band and held in place.

Although LAGB appears easier than many of the procedures done to treat obesity, there is a definite learning curve. A number of surgical misadventures have been reported, including gastric perforation, splenic injury, and malpositioning of the band.

COMPLICATIONS

Band slippage (anterior, posterior, or concentric) may occur even after proper placement, resulting in intolerance of oral intake and vomiting. Such complaints are an indication

for an upper GI series, which usually reveals dilatation of the proximal pouch and rotation of the band [see Figure 8]. Initial treatment consists of evacuating all saline from the band. Frequently, however, the proximal pouch does not return to its normal size, and symptoms recur or fail to resolve. Laparoscopic or open revision of the banding procedure is then required; if the patient also has not lost a sufficient amount of weight, conversion to GBP may be recommended. It is noteworthy that band erosion into the stomach, a not infrequent complication of the use of mesh in VBG or in the Angelchik prosthesis for gastroesophageal reflux treatment, has not been frequently reported. Longer follow-up is necessary to evaluate the true extent of this risk.

As after any form of gastroplasty, the patient may fail to lose weight or may regain lost weight. Inappropriate eating behaviors (e.g., intake of high-calorie sweets) are the most likely cause. If obesity-related comorbid conditions persist, conversion to proximal GBP is appropriate.

Figure 8 Laparoscopic adjustable gastric banding. Contrast studies illustrate (a) a normally positioned laparoscopic adjustable gastric band and (b) a slipped band.

OUTCOME EVALUATION

How successful LAGB is at achieving weight loss over the long term remains unclear. The adjustability and reversibility of the operation, as well as the decreased disability that results, make it attractive to both patients and physicians. The procedure appears to avoid some of the major postoperative complications associated with open GBP (e.g., incisional hernia, marginal ulcer, and stomal stenosis). Band slippage remains a major postoperative concern, however, though the incidence of slippage does appear to decrease as the surgeon's experience with the procedure increases. More significant, there appears to be a high frequency of failed weight loss—as high as 15 to 20% of all patients undergoing the procedure and possibly even higher. European data confirm that there is a significant failure rate but also suggest that the remaining patients achieve a degree of weight loss approaching that seen with proximal GBP. Whether these reports will withstand the scrutiny of long-term follow-up remains to be seen.

Open Proximal Gastric Bypass

Proximal GBP results in greater weight loss than the gastric restrictive procedures (see above) and carries a lower incidence of weight regain; consequently, it is often considered the gold standard for bariatric surgery. Compared with the version of GBP performed at our institution, the original GBP created a much larger proximal gastric pouch and a much wider anastomotic opening, and it was often associated with inadequate weight loss. In the later version, three superimposed 55 or 90 mm staple lines are placed across the proximal stomach in such a way as to create a gastric pouch no larger than 30 ml with a Roux limb at least 45 cm long and a stoma no larger than 1 cm [see Figure 9]. This anatomic situation is largely replicated when GBP is done laparoscopically, but an isolated gastric pouch is created with stapled transection of the stomach.

OPERATIVE TECHNIQUE

Step 1: Initial Incision and Abdominal Exploration

Once the patient is anesthetized, the abdomen receives a thorough, careful cleansing with povidone-iodine and is draped in a sterile fashion. An upper midline incision is made and extended through the fascia alongside the xiphoid process to facilitate cephalad exposure. The incision is routinely carried down to the supraumbilical area. The deep layer of subcutaneous fat can often be separated bluntly with aggressive lateral traction applied by the surgeon and the assistant, and the midline usually can then be identified for fascial incision. The electrocautery is used to enter the abdominal cavity, and a thick layer of subfascial preperitoneal fat is often encountered before entry into the peritoneal cavity. Abdominal exploration is undertaken in every patient, including examination of the liver for possible signs of liver disease. Other incidental findings may become apparent as well.

Troubleshooting Unexpected significant liver disease is occasionally discovered at the time of operation. If the patient has cirrhosis without portal hypertension, one should perhaps

Figure 9 Open proximal gastric bypass. Depicted is the completed procedure.

proceed with bypass if the patient's comorbid conditions make it mandatory; liver transplantation carries increased risk in morbidly obese patients. The gallbladder should be palpated for gallstones, which, if found, may be an indication for cholecystectomy at the time of the bypass procedure. If there are no visual or palpable gallbladder abnormalities, intraoperative ultrasonography may be used to examine the gallbladder.

It is not unusual to discover other previously unrecognized conditions during GBP, primarily because symptoms may not be obvious in morbidly obese patients and because their large size tends to make radiologic imaging difficult or even impossible. For example, intraoperative discovery of pelvic cysts and tumors is not uncommon in obese female patients. Such lesions may be excised during GBP; on occasion, if they appear benign and their location prevents safe excision, they may be managed with careful follow-up.

Step 2: Mobilization of Esophagus

The bypass procedure itself is begun by mobilizing the distal esophagus and encircling it with a soft rubber drain 0.5 in. in diameter. The gastrohepatic omentum is bluntly entered at a point overlying the caudate lobe, with care taken to look for and avoid injury to an aberrant left hepatic artery. The phrenoesophageal ligament overlying the anterior and lateral distal esophagus is sharply incised to facilitate subsequent blunt mobilization of the distal esophagus. To prevent esophageal injury, the nasogastric tube is carefully palpated within the lumen of the esophagus during mobilization, and blunt dissection proceeds widely around this important landmark. Laterally, dissection must be at the level of the esophagus or higher.

Troubleshooting If dissection is too low laterally, it may result in blunt injury to the short gastric vessels, bleeding, and the need for urgent splenectomy, which is no easy task in a morbidly obese patient. In addition, it may lead to creation of an inappropriately large pouch by keeping the surgeon from recognizing that some of the stomach is above the level at which the encircling rubber drain is placed.

Step 3: Division of Mesentery and Dissection around Stomach

Once the esophagus is mobilized, the assistant's left hand is placed through the gastrohepatic omental opening behind the stomach wall on the lesser curvature. The space between the first and second branches of the left gastric artery is then identified as a landmark for location of the gastric staple line, both to ensure that the pouch created is no larger than 30 ml and to prevent injury to the left gastric artery, which usually runs cephalad to this location. With the surgeon's posterior finger pressing anteriorly to place tension on the tissue, a fine-tip right-angle clamp and the electrocautery pencil are used to divide the mesentery carefully at this level immediately alongside the stomach wall so as to create a mesenteric opening that will admit a large right-angle clamp.

The avascular tissue on the posterior wall of the stomach is then bluntly dissected between the opening in the gastrohepatic omentum and the lateral angle of His, which is identified by the encircling rubber drain. The blunt tip of a large 28 French red rubber tube is placed behind the stomach in a medial-to-lateral direction along this dissected path to encircle the stomach [see Figure 10]. The open end of the red rubber tube is subsequently brought through the previously created mesenteric opening with a large right-angle clamp. The stomach is now ready for stapling, and the red rubber tube serves as a guide for introduction of the stapler. At this point, all intraluminal tubes and devices (e.g., the nasogastric tube and the esophageal stethoscope) are removed from the esophagus by the anesthetist.

Troubleshooting When a tube is inadvertently stapled within the stomach, excising it from the nontransected

Figure 10 Open proximal gastric bypass. After dissection of the avascular tissue on the posterior gastric wall, a red rubber catheter is passed through the resulting space to encircle the stomach.

gastric staple line can be a technical challenge. To remove the stapled tube, it is generally necessary to use a stapler to transect the stomach, thereby creating the potential for significant injury to the gastric tissue unless the transection is precisely superimposed over the previous staple line. The tube can then be excised from each side (proximal and distal) of the divided gastric staple lines.

Step 4: Creation and Mobilization of Roux Limb and Jejunojejunostomy

The ligament of Treitz is identified, and the jejunum is measured to a point 45 cm beyond the ligament—or somewhat more distally to enhance mobilization of what will become the Roux limb if the mesentery appears foreshortened—at which point the jejunum is divided with a stapler. An 8 to 12 cm segment of jejunum may be resected at this point to create a larger mesenteric defect, which should facilitate mobilization of the limb to the proximal stomach. Mesenteric dissection is carried posteriorly in fat with the sequential application of clamps until further dissection appears either unnecessary for mobilization or unwise (i.e., likely to cause mesenteric vascular injury or ischemia of the Roux limb).

A side-to-side jejunojejunostomy is then created with a 60 mm linear stapler at least 45 cm beyond the initial point of jejunal division for standard proximal GBP. Some surgeons perform this anastomosis 150 cm downstream for the long-limb modification of the procedure used in superobese patients [see Operative Planning, Choice of Surgical Procedure, above] or even further distally for the distal GBP modification, which greatly enhances malabsorption. It is important not to narrow the efferent lumen at the jejunojejunostomy site, particularly with the longer-limb modifications, in which the lumen at the distal end of the Roux limb may be quite small. The enterotomies made to allow placement of the stapler can usually be closed with a 55 mm stapler loaded with 3.5 mm staples; however, if stapling would cause undue narrowing of the lumen, the closures should be handsewn instead.

Troubleshooting It may be preferable to mobilize the Roux limb before committing to stapling the stomach so that it can be determined whether the limb can be extended to reach the proximal stomach without being placed under tension. In those rare cases in which the mesentery is too foreshortened to permit the limb to reach the proximal stomach, it is advisable to change the procedure to VBG or gastric banding rather than create a gastrojejunal anastomosis under tension and thereby incur the increased risk of leakage.

Step 5: Gastric Stapling and Gastrojejunostomy

The Roux limb is brought through the mesentery of the transverse colon with blunt dissection and then brought up to the proximal stomach. The 55 or 90 mm stapler, loaded with 4.8 mm staples, is guided behind the stomach by inserting its open-mouthed end into the lumen of the previously positioned red rubber tube. Once it is determined that the staple line will reach completely across the stomach and that the stomach is not folded on itself, the stomach is stapled three times in such a way that the three staple lines are superimposed [see Figure 11].

Figure 11 Open proximal gastric bypass. The stomach is stapled to create the small proximal pouch. The stapler is fired three times to create three superimposed staple lines, thereby decreasing the risk of staple line disruption.

A 1 cm anastomosis is created between the proximal stomach pouch and the Roux limb. We prefer a handsewn anastomosis for this procedure, using an outer layer composed of interrupted 2-0 or 3-0 silk sutures and an inner layer composed of a continuous absorbable 3-0 polyglycolic acid (Dexon) suture. When the posterior aspect of the anastomosis is complete, a 30 French dilator is placed orally by the anesthetist and is guided through the anastomosis by the surgeon to ensure that the stoma has the appropriate diameter [see Figure 12]. The anterior aspect of the anastomosis is then completed.

Troubleshooting A significant concern for many bariatric surgeons has been a high incidence of staple line disruption causing failed weight loss or weight regain; in one series, the incidence of such disruption was 35%. To minimize this risk, some surgeons advocate transecting the stomach. Currently, this step is routinely carried out as part of a

Figure 12 Open proximal gastric bypass. When the posterior aspect of the gastrojejunal anastomosis has been completed, a 30 French dilator is placed through the stoma to confirm that the opening is correctly sized.

laparoscopic GBP. In an open GBP, one may transect the stomach either by applying a linear cutting stapler with 3.5 or 4.8 mm staples (depending on the estimated gastric wall thickness) or by inserting two parallel noncutting transverse anastomosis (TA)-90 staplers and cutting between them with a scalpel after the staplers are fired. Other surgeons, however, prefer to leave the stomach undivided and oversew the staple line. In our version of open GBP, we find that placing three or four precisely superimposed staple lines reduces the incidence of staple line disruption to less than 2%.

Another advantage of gastric transection besides reduction of staple line disruption is that it allows the Roux limb to be brought up to the gastric pouch via a retrocolic and retrogastric tract, which is substantially shorter and places less tension on the limb. This approach is particularly helpful in severely obese patients with a fatty and foreshortened mesentery, in whom it is difficult to free the Roux limb sufficiently to reach the proximal stomach without tension. The possibility that gastric transection may prove helpful in a specific patient is another reason why it is advisable to delay stapling the stomach until the Roux limb has been mobilized.

Step 6: Assessment of Anastomosis

When the entire anastomosis is complete, the dilator is removed and an 18 French nasogastric tube is advanced by the anesthetist while the tip is carefully guided through the anastomosis by the surgeon. The Roux limb is occluded with the assistant's left hand or with an atraumatic intestinal clamp, and the esophagus is occluded by placing tension on the rubber drain surrounding it while the anesthetist injects a series of 10 ml aliquots of methylene blue dye through the nasogastric tube to determine whether the anastomosis is leaking. A total of 30 to 60 ml of methylene blue must usually be injected; lesser amounts will not stress the suture line enough to constitute an adequate test. Alternatively, the anastomosis can be tested by performing intraoperative gastroscopy. If leakage is present, the air insufflated during the procedure will be visible bubbling from the leaking areas when the air-distended anastomosis is submerged in irrigation fluid.

Troubleshooting When an intraoperative leak is identified, the area of leakage should be oversewn with silk sutures until injection of additional methylene blue dye via the nasogastric tube yields no further leakage. The most difficult area to repair is the posterior suture line, which is quite close to the gastric staple line. Posterior leaks are usually repaired by reinforcing the posterior suture line with additional sutures between the excluded stomach and the jejunal limb; often, the entire posterior suture line is oversewn. In addition, a viable pedicle of omentum may be mobilized and placed around the anastomosis for further reinforcement. Closed suction drains may also be placed in this area, both to detect possible postoperative leakage and to control a postoperative leak or fistula.

Finally, a gastrostomy tube may be placed in the excluded portion of the stomach. This measure provides postoperative decompression, which should prevent the development of undue tension on the Roux limb as a result of gastric distention. In addition, it establishes a route for enteral

feeding if a fistula develops. Fortunately, such fistulas are rare. When they do occur, they often heal if (1) they are well drained, (2) there is no distal obstruction or local abscess, and (3) the patient is receiving nutritional support with no oral intake. A gastrostomy tube should also be placed in the distal gastric pouch when extensive adhesions from a previous procedure or a difficult gastric reoperation increase the risk of postoperative gastric distention.

Step 7: Closure

When the absence of leakage is confirmed or when any leaks identified have been controlled, the tip of the nasogastric tube may be positioned further down in the Roux limb and left to continuous suction overnight. All mesenteric defects—at the jejunojejunostomy, at the mesocolon, and behind the Roux limb (Peterson hernia)—are then closed to prevent an internal hernia. The abdominal fascia is reapproximated with a continuous double-looped No. 2 suture, subcutaneous tissues are irrigated with a crystalloid solution, and the skin is closed with skin staples. No subcutaneous sutures or drains are used in routine cases.

COMPLICATIONS

Proximal GBP is associated with a significant incidence of stomal stenosis and with marginal ulcer.⁵⁵ The former responds to endoscopic stomal dilatation, and the latter usually responds to proton pump inhibitor (PPI) therapy. Addition of sucralfate to this regimen may be helpful. The risk of marginal ulcer appears to be increased in smokers and in patients who consume nonsteroidal anti-inflammatory drugs (NSAIDs). We routinely discourage NSAID use after GBP. Perforation of the proximal gastric pouch, probably arising from perforation of a deep ulcer, has been seen with administration of high-dose NSAIDs or with untreated ulcer diathesis.

Iron, vitamin B₁₂, and folic acid deficiencies may occur but can usually be corrected with oral supplementation³²; accordingly, GBP patients, like VBG and gastric banding patients, should be advised to take a multivitamin daily for life. Compared with gastropasty and gastric banding, GBP results in significantly lower serum hemoglobin and iron concentrations. This is primarily a problem in menstruating women. All menstruating women who have undergone GBP should be treated prophylactically with supplemental oral ferrous sulfate, 325 mg/day. As many as six iron tablets a day may be required if menstrual bleeding is heavy. Hormonal therapy to control or temporarily eliminate menses may be helpful. On occasion, intramuscular iron injections or, rarely, hysterectomy may be necessary. The risk of vitamin B₁₂ deficiency is higher after GBP than after gastropasty or gastric banding, but this condition can be prevented with supplemental oral vitamin B₁₂, 500 mg/day. A few patients may require (or prefer) monthly B₁₂ injections, which they can learn to administer themselves.

Concerns have been expressed that GBP can lead to other divalent cation deficiencies. Our group has not encountered zinc deficiencies 5 to 9 years after GBP, though we have observed calcium deficiencies leading to osteoporosis, which may take many years to become manifest and may not be biochemically evident because of normal serum calcium levels. It is therefore recommended that all GBP patients

take oral calcium supplements. Some may require vitamin D supplementation. Magnesium deficiencies should be treated with MgSO_4 supplementation.

Although nutritional deficiencies do not appear to be a greater problem with long-limb GBP than with standard proximal GBP, monitoring patients for possible malabsorption of the fat-soluble vitamins A, D, and E after long-limb GBP is advisable.

BPD may be associated with all of the complications seen after GBP. In addition, patients who undergo BPD may experience diarrhea, severe protein malnutrition (manifested as hypoalbuminemia), and deficiencies of vitamins A (manifested as severe night blindness), D (manifested as severe osteoporosis), and E.⁵⁰ Hypoalbuminemia may respond to oral pancreatic enzymes but often must be treated with total parenteral nutrition. In some patients, it may prove necessary to lengthen the absorptive intestinal tract from 50 cm to 200 cm.

OUTCOME EVALUATION

A series of 672 open proximal GBP procedures reported a 1.2% incidence of anastomotic leakage with peritonitis, a 4.4% incidence of severe wound infections (defined as infections serious enough to delay hospital discharge), an 11.4% incidence of minor wound infections and seromas (which were easily treated at home), a less than 1% incidence of gastric staple line disruption with the use of three superimposed applications of a 90 mm linear stapler, a 15% incidence of stomal stenosis, a 13% incidence of marginal ulcer, a 16.9% incidence of incisional hernia, and a 10% incidence of cholecystitis necessitating cholecystectomy.⁴⁷ Gallstones developed in 32% of the GBP patients who had a normal intraoperative gallbladder sonogram within 6 months of surgery, and sludge was observed in another 10%. In a multicenter randomized, prospective trial, the incidence of gallstones within 6 months of GBP was reduced from 32% to 2% by giving patients ursodeoxycholic acid, 300 mg twice daily.⁵⁶ Gallstone formation beyond 6 months is uncommon. The operative mortality in this series was less than 1%. Patients with respiratory insufficiency of obesity had an operative mortality of 2.2%, whereas those without pulmonary dysfunction had an operative mortality of 0.4%.

Neither the data from this randomized, prospective trial nor the data from selective studies support the contention that VBG is safer than GBP. Although GBP includes one more anastomosis than VBG, complications such as leaks and peritonitis occur with both operations. A common criticism of GBP is that it is difficult to evaluate the distal gastric pouch and duodenum after the operation. Such evaluation, however, can be done in 75% of patients by means of retrograde passage of an endoscope into the duodenum and the stomach and in other patients by means of percutaneous distal distention gastrography. Bleeding from either the distal gastric pouch or a duodenal ulcer is rare. Gastric mucosal metaplasia of the bypassed portion of the stomach may occur in some 5% of patients after retrograde endoscopy, a finding that has raised concerns regarding the risk of carcinoma arising at that location. To date, however, although many thousands of these procedures have been performed over the past four decades, few cases of cancer in the bypassed stomach have been reported.

Laparoscopic Gastric Bypass

Laparoscopic GBP is currently the most popular bariatric procedure in the United States, both because of the rapid weight loss it achieves and because of the strong overall surgical trend toward minimally invasive approaches. As noted [see Operative Planning, Laparoscopic versus Open Approach to Bariatric Surgery, *above*], laparoscopic GBP achieves the same weight-loss results as open GBP but yields less pain, reduced disability, and a shorter duration of hospitalization. Physiologically, laparoscopic GBP results in less operative trauma than open GBP, less impairment of pulmonary function, and a less pronounced stress response. In addition, the laparoscopic technique is associated with lower incidences of major wound infections and incisional hernias. Accordingly, we recommend laparoscopic GBP over any other bariatric procedure.

Laparoscopic GBP poses significant technical challenges, even for surgeons with advanced laparoscopic skills. Most of the variations seen at different institutions are related to various techniques for creation of the gastrojejunal anastomosis, with some groups using a circular stapler, others a linear stapler, and still others a handsewn technique. The anvil of the circular stapler may be placed within the proximal gastric pouch either by means of flexible upper GI endoscopy, through an approach similar to the snare-and-wire technique used for placement of a percutaneous endoscopic gastrostomy (PEG) tube [see 5:18 *Gastrointestinal Endoscopy*], or by means of a gastrotomy of the stomach before pouch creation for intra-abdominal anvil placement, followed by staple closure of the gastrotomy. Peroral placement of the stapler's anvil can be problematic: even the small 21 mm anvil is hard to pass through the proximal esophagus in some patients. To facilitate esophageal passage, a "flip-top" anvil design has been introduced. With this design, a 25 mm anvil can generally be passed without undue difficulty, thereby lowering the risk of postoperative stenosis. We routinely use the linear stapling method to create the gastrojejunal anastomosis; it is easier than circular stapling in this setting, and there is no risk of esophageal trauma from anvil passage.

OPERATIVE TECHNIQUE

Step 1: Initial Access and Trocar Placement

Initial access to the abdomen is obtained through a small left subcostal incision. Gas is insufflated into the abdomen via a Veress needle to a pressure of 15 mm Hg; on occasion, a pressure of 18 to 20 mm Hg may be necessary. A dilating 5 mm trocar is then placed in this location. Many surgeons use commercially available trocars that allow direct vision through the scope during passage of a 12 mm trocar. We encourage preinsufflation of the abdominal cavity before such a device is employed so as to enhance identification of the peritoneal sac and avoid organ injury. Additional trocars are placed in specific locations [see *Figure 13*]. The liver is retracted with a metal Nathanson liver retraction device anchored to the bed, which is inserted after a 5 mm sharp trocar is used to develop a tract into the abdominal cavity in the subxiphoid position and removed. If the left lateral section of the liver is very large (as in patients with steatosis), additional liver retractors may be necessary.

Figure 13 Laparoscopic gastric bypass (GBP). Shown are the trocar incision sites for laparoscopic GBP.

On occasion, the enlarged fatty falciform ligament must be dissected from the anterior abdominal wall with an ultrasonic scalpel or a bipolar cautery device. The advent of long laparoscopic graspers, staplers, and energy dissectors has facilitated operating on the proximal stomach and allows the use of trocar locations away from the abdominal midline. A 12 mm port placed in the right paramedian position serves as the surgeon's primary operative port; two lateral subcostal 5 mm ports allow both surgeon and assistant to employ two-handed techniques for the entire procedure. In most patients, a 45° angled viewing 5 mm laparoscope is inserted via a supraumbilical 5 mm trocar. A longer 10 mm scope may enhance visibility, particularly for especially heavy or tall patients, in whom a 5 mm scope may be subject to damage from excessive torque. High-definition imaging improves visualization during the procedure.

Step 2: Creation of Roux Limb and Jejunojunctionostomy

In most reports of laparoscopic GBP, regardless of how the gastrojejunostomy is done, the approach to creating the Roux limb is essentially the same. The patient is placed in a supine position, and graspers are used to bring the omentum upward into the upper abdomen so that the transverse colon and the underlying mesocolon are exposed. Graspers are then placed on the transverse mesocolon and used to elevate it anteriorly so that the ligament of Treitz is exposed. The position of the ligament of Treitz is confirmed by careful manipulation and verification that the bowel is attached to the retroperitoneum at this location; this may be a more difficult task in patients who have previously undergone abdominal procedures.

With the help of a measuring instrument, the small bowel is measured to a point 50 cm from the ligament of Treitz, where it is transected with the endoscopic gastrointestinal

anastomosis (GIA) stapler, loaded with 2.5 mm staples. A 0.5 in. Penrose rubber drain may be sutured to the cut end of the Roux limb so that it is not confused with the other cut end of the bowel. The Roux limb is then measured to a length of 45 to 60 cm. (As in open GBP, the Roux limb should be significantly longer—up to 150 cm—if the long-limb modification is being performed.) The afferent side of the previously transected small bowel is then attached with a simple absorbable suture to the proposed jejunojunctionostomy site on the Roux limb. Intracorporeal suturing is facilitated by using an automatic suturing device. Positioning is important: the afferent limb should be kept toward the mesocolon (toward the left side of the surgeon's field of view), with the Roux limb brought toward the surgeon (visualized on the right side of the operative field of view).

Two holding sutures are placed, one proximal to the proposed site of the enterotomy for the anastomosis and the other distal to this site, to help manipulate the bowel onto the stapler. A small (1 cm) enterotomy is made with the electrocautery in each of the two adjacent bowel limbs in preparation for passage of the linear stapler, loaded with 2.5 mm staples in a 60 mm cartridge, into the bowel. The stapler is then fired, creating a 60 mm side-to-side anastomosis. A suture is placed at the staple line to elevate the corner of the anastomosis for subsequent stapled closure of the defect, and a third holding suture is placed at the midpoint of the enterotomy. The three sutures are grasped to facilitate closure of the enterotomy by another application of the linear stapler, with great care taken to avoid narrowing at the junction of the Roux limb and the large common channel of the anastomosis. To facilitate closure without obstruction, all three knots should be visible above the stapler, but tissue amputation should be minimal. Once completed, the anastomosis is inspected both for integrity and for possible narrowing. At this point, cephalad traction is applied to the remaining suture (in the medial position) to facilitate placement of a continuous suture to close the mesenteric defect.

Some surgeons prefer to create a loop gastrojejunostomy, thereby avoiding the technical challenges associated with creating a Roux limb laparoscopically. This approach was abandoned years ago in open GBP because of the unacceptably high incidence of postoperative bile reflux and the increased severity of complications resulting from high output of digestive juices when leakage occurred at the gastrojejunal anastomosis; it should be abandoned in laparoscopic GBP as well. The practice of using such suboptimal methods for the purpose of performing this complex operation more expeditiously is poorly conceived.

Step 3: Passage of Roux Limb

Next, the greater omentum is divided from its free edge to its junction with the transverse colon so that the limb can be brought up in an antecolic fashion between the divided halves of the omental "apron," which reduces tension on the limb. Alternatively, a retrocolic, retrogastric tunnel may be created so that the Roux limb can be advanced to the proximal stomach for anastomosis. The retrocolic, retrogastric approach is superior if the antecolic approach appears to be placing undue tension on the limb as it is advanced to the proximal pouch. For retrocolic passage, the ligament of Treitz is identified

by lifting the transverse mesocolon anteriorly, and a spot 1 to 2 cm anterior and to the left of the ligament is chosen as the starting point for electrocautery dissection. The middle colic artery should be medial to this point of entry into the mesocolon. The goal of the dissection is to identify the posterior wall of the stomach, which may be difficult in patients who are extremely obese, have a fatty, foreshortened mesocolon, or have previously undergone abdominal surgery.

Once the stomach is visible, it is grasped and elevated through the mesocolic window, and the end of the Penrose drain is grasped and brought through the mesocolic defect into the lesser sac. When the Penrose is in place in the lesser sac, the omentum is pulled down from the epigastrium to allow visualization of the stomach, and the patient is placed into a steep reverse Trendelenburg position. The Penrose drain will be exposed when the cutting stapler is employed to create the proximal gastric pouch, and care must be taken to avoid stapling the drain.

There has been some controversy regarding the relative merits and deficiencies of antecolic and retrocolic techniques for passage of the Roux limb. The original open GBP often made use of a retrocolic, antegastric approach. The subsequent evolution of gastric transection methods led to a retrocolic, retrogastric approach to limb passage, which decreased the distance the limb had to travel to reach the proximal stomach and reduced the tension placed on the gastrojejunal anastomosis. Eventually, the antecolic, antegastric technique was introduced; this approach became popular with laparoscopic surgeons because it usually made the procedure faster to perform. The advantages of this technique were confirmed by a study that prospectively compared 33 consecutive patients who underwent retrocolic LRYGB with 33 who underwent antecolic LRYGB over a 3-year follow-up period.⁵⁷ The results suggested a similar decrease in BMI (from 45 kg/m² before operation to 34 kg/m² at 36 months) and a similar incidence of complications (e.g., internal hernias and strictures). Operating time was significantly shorter for the antecolic procedure (mean, 188 minutes) than for the retrocolic procedure (mean, 219 minutes).

Other issues that have been raised in comparing the two techniques include the risk of internal hernias through mesenteric defects and the various risks inherent in an anastomosis performed under tension (e.g., leakage, ischemic stricture, and ulceration). In addition, retrocolic passage of the Roux limb during LRYGB leaves a short segment of the limb that is not easily visualized; unrecognized twisting of this segment may occur and lead to postoperative obstruction. A 2007 study that evaluated 754 LRYGB patients (300 retrocolic, 454 antecolic) over a median follow-up period of 16 months found that the rate of complications (e.g., surgical exploration for intestinal obstruction and internal hernias) was higher after the retrocolic procedure.⁵⁸ Another 2007 study that evaluated 353 LRYGB patients (218 retrocolic, 135 antecolic) over a mean follow-up period of 28 weeks found that the incidence of postoperative gastrojejunal leakage was higher after the antecolic procedure.⁵⁹ These varying study outcomes suggest that a prospective, randomized trial will ultimately be required to determine whether antecolic Roux limb passage is superior or inferior to retrocolic passage with respect to outcomes or complication rates.

Both techniques continue to be employed today, and the current evidence is not sufficient to support a blanket recommendation favoring one over the other. We would maintain, however, that if undue tension is evident when the Roux limb is passed via the antecolic pathway, it is advisable to switch to the shorter route available via the retrocolic, retrogastric pathway.

Step 4: Dissection around Stomach and Creation of Gastric Pouch

The mesentery of the lesser curvature is transected with a bipolar electrocautery device to provide hemostasis. Despite the potential for problems with transection of the neurovascular bundle, no clear evidence of such problems has been found in hundreds of procedures performed with this access technique. Dissection posterior to the stomach is performed in the avascular free plane of the lesser sac. Additional dissection along the lesser curvature is not recommended, because it may increase the devascularization of the pouch. Further dissection is done at the angle of His to create a connection with the posterior gastric space. A linear endoscopic GIA stapler loaded with 3.5 mm staples in 60 mm cartridges is then employed in sequential firings to transect the stomach and create the proximal gastric pouch; three or four firings are usually necessary [see Figure 14]. When revisional bariatric surgery is performed on the previously operated-on stomach or when buttressing materials are used to reinforce the staple line, a staple height of 4.8 mm is usually required.

Step 5 (Circular Stapling): Placement of Stapler in Gastric Pouch

As noted (see above), surgeons use several different techniques to complete the gastrojejunal anastomosis. If a linear stapler is used, the next step is gastrojejunostomy [see Step 6b (Linear Stapling), below]. With the technique reported in Wittgrove's original description of the procedure,⁶⁰ however, in which the anvil of a circular stapler is passed down the

Figure 14 Laparoscopic gastric bypass (GBP). Much as in open GBP, a linear endoscopic gastrointestinal anastomosis (GIA) stapler is fired three times to transect the stomach and create the gastric pouch.

patient's esophagus, the next step in the procedure is to have an assistant perform flexible upper GI endoscopy of the gastric pouch. The pouch wall is transilluminated by the endoscope light, and a site is chosen for the gastrojejunostomy. The endoscopist then places an endoscopic snare, which can be seen pressing against the tissue of the pouch wall. A small opening is made in the pouch with the electrocautery scissors so that the snare can be pushed through the gastric wall at this location. The snare is then used to grasp a wire placed through a needle across the abdominal wall in the left abdomen, and snare and wire are withdrawn through the mouth along with the scope.

The anvil of the stapler is attached to the end of the wire that was drawn through the mouth, and the surgeon pulls on the other end of the wire to deliver the anvil through the mouth, down the esophagus, and into the gastric pouch, where it can be visualized. The electrocautery is used to enlarge the opening in the gastric wall slightly, and the stem of the stapler is then brought through the gastrotomy. To prevent anastomotic leakage after stapling, the gastrotomy should be no larger than the diameter of the stem; if it is too large, it can be closed around the stem by placing one or two simple sutures.

An alternative technique for anvil placement in the pouch involves making a gastrotomy distal to the planned staple line before transection of the stomach. After the anvil is introduced into the abdomen via a dilated trocar site, a long sharpened dissector is employed to grasp a suture tied to the anvil stem. The dissector is then passed into the lumen of the stomach and used to perforate the future pouch in location that is appropriate for the eventual anastomosis. Once the anvil stem has been advanced through the perforation, the dissector is withdrawn. Stapling of the stomach may include amputation of the gastrotomy site. The pouch is created by stapling around the anvil and thus can be made very small.

Troubleshooting Difficulty in passing the anvil perorally may arise at the level where the trachea separates from the esophagus in the deep pharynx. This difficulty can usually be overcome either by having the endoscopist perform a jaw-thrust maneuver or by placing a large laryngoscope blade deep in the pharynx to make the anvil visible in the proximal esophagus and then nudging the anvil forward with either the tip of the blade or a McGill forceps. Transiently deflating the endotracheal tube balloon may also help. Occasionally, a large, blunt esophageal dilator is used to place pressure on the top of the anvil. Given the potential for esophageal injury if the anvil will not advance, it is important not to apply excessive force. In one case from our experience, the anvil became lodged in the proximal esophagus beyond the laryngoscopic view, and the long suture holding it broke; retrograde passage of an esophageal dilator placed via a gastrotomy in the pouch was required to dislodge the anvil. Other surgeons who use wire to draw the anvil down the esophagus have identified nontransmural esophageal injuries on postoperative contrast studies or have seen subcutaneous emphysema in the neck after operation. There is at least one case report describing an esophageal perforation with this technique.

Step 6a (Circular Stapling): Gastrojejunostomy

In the circular stapling technique, the stapled end of the Roux limb is opened to permit introduction of the stapler. A

12 mm trocar site in the left upper quadrant is dilated so that the circular stapler can be inserted through the abdominal wall without the need for a trocar. Lubrication is helpful for this step, and covering the device with a sterile plastic bag helps to protect the wound from contamination when the device is extracted. The transabdominal stapler then cannulates the Roux limb. The stapler is advanced 3 to 4 cm down the limb, and the spike on the body of the device is brought through the antimesenteric portion of the bowel by unscrewing the stapler under direct vision. Once the stapler has been opened completely, it is laparoscopically joined to the anvil protruding from the gastric pouch, then closed and fired.

Once fired, the stapler is removed from the abdominal wall, and a balloon trocar device is used to close the dilated abdominal wall opening. A single firing of the endoscopic GIA stapler, loaded with 2.5 mm staples, is often all that is required to close the enterotomy left from passage of the stapler. Interrupted or continuous absorbable sutures are then placed around the stapled anastomosis to provide added security and reduce tension on the staple line.

Step 6b (Linear Stapling): Gastrojejunostomy

Initially, a continuous posterior row of nonabsorbable suture material is placed to secure the Roux limb to the posterior gastric pouch. An enterotomy and a gastrotomy are performed that are large enough to admit the jaws of the endoscopic GIA stapler, which is loaded with 3.5 mm staples in a 45 mm cartridge for a side-to-side anastomosis [see Figure 15] by means of the same techniques employed

Figure 15 Laparoscopic gastric bypass. A 30 French dilator is placed into the proximal gastric pouch before closure of the gastrojejunal anastomosis with the endoscopic gastrointestinal anastomosis (GIA) stapler.

in creating the jejunojejunostomy. The cartridge is inserted to its full length and fired to create an inner stapled layer [see Figure 16]. We use the full length of the staple cartridge because we have found that our technique (a complete two-layer anastomosis that includes 360° oversewing of the anastomosis over a 30 French dilator or a flexible 9 to 11 mm gastroscope) can lead to obstruction if the full cartridge length is not employed. The remaining gastroenterotomy defect is closed in two layers with continuous sutures (absorbable for the inner layer, nonabsorbable for the outer).

In our experience, using the linear stapler for the gastrojejunostomy simplifies the procedure, reduces operating time, and eliminates the concerns about injury to the body of the esophagus that arise with passage of the circular stapler.

Step 6c (Handsewn Anastomosis): Gastrojejunostomy

Some surgeons employ laparoscopic suturing techniques to create a handsewn gastrojejunostomy, usually with a single layer of continuous nonabsorbable suture material. In particular, robotic surgery techniques usually include hand suturing, using the robotic effectors to grasp the tissue and the needle and, ultimately, to tie the suture. Robotic techniques are hampered by the setup time required for placement of the robotic arms, but they have been touted as being particularly useful for operating on superobese persons, in whom manipulation of traditional laparoscopic instruments is made difficult by the extreme thickness of the abdominal wall, which interferes with the trocar's fulcrum effect. In such cases, use of a robotic technique appears to improve the ergonomics of the procedure and relieve the surgeon's hand and arm fatigue.

Step 7: Assessment of Anastomosis

In every case, regardless of which anastomotic technique is employed, flexible upper GI endoscopy is performed to assess the anastomosis. The Roux limb is occluded with an intestinal clamp to prevent excessive bowel and distal gastric dilatation. The patient is placed in the supine position, and

Figure 16 Laparoscopic gastric bypass. The gastrojejunal anastomosis is closed with the linear endoscopic gastrointestinal anastomosis (GIA) stapler.

the area around the anastomosis is irrigated with saline; the presence of air bubbles, easily detectable in the irrigant, indicates that the anastomosis is leaking. In most cases, the pouch and the Roux limb can be distended tightly, and even tiny air leaks are reinforced with additional sutures. The anastomosis and the staple lines are visualized, and the endoscope is navigated through the anastomosis into the Roux limb whenever possible. After adequate visualization and testing, the gas is suctioned from the intestine, the Roux limb is unclamped, and the endoscope is removed. Alternatively, some surgeons prefer to distend the anastomosis with methylene blue dye to exclude leakage.

Step 8: Closure

Finally, a 10 mm closed suction drainage tube may be placed adjacent to the anastomosis to permit monitoring for postoperative leaks. In our program, we no longer do this on a routine basis. If a drain is placed, it is usually removed after the patient begins oral intake. Selected patients undergo upper GI series to evaluate for postoperative leakage [see Figure 17]. This radiographic study is considered mandatory in patients with equivocal postoperative signs and symptoms of leakage, though surgical reexploration may be preferable and is a more definitive assessment in such patients.

In antecolic Roux-en-Y procedures involving division of the greater omentum, the lateral tongue of greater omentum may be wrapped in a lateral-to-medial direction posteriorly around the gastrojejunostomy, then sutured to the anterior pouch tissue so as to reinforce the anastomosis. We do not do this routinely—only when we have technical concerns about the integrity of the anastomosis. We also sometimes use the distal gastric remnant as a live tissue patch over areas of concern in a difficult anastomosis. The liver retractor is removed under direct vision to ensure that no bleeding occurs. When dilating trocars have been employed, the trocar

Figure 17 Laparoscopic gastric bypass. Flexible upper gastrointestinal endoscopy is performed to assess the completed anastomosis.

sites are not routinely closed. Trocar sites manually dilated to permit extraction of a specimen (e.g., gallbladder) or passage of a circular stapler should be closed with sutures to avoid risk of hernia formation; we have found that such closure increases postoperative incisional pain at these sites. Skin wounds are closed with minimal subcuticular sutures, and the epidermis is reapproximated with commercially available skin closure adhesives.

HAND-ASSISTED LAPAROSCOPIC GASTRIC BYPASS

Because total intracorporeal laparoscopic GBP is such a challenging technical adventure, a hand-assisted version of the procedure was developed.⁶¹ This technique served as a bridge to the total intracorporeal approach, in that it made it possible to learn the technical aspects of a difficult, highly advanced laparoscopic procedure while enjoying the security provided by the presence of a hand within the abdomen for palpation and manipulation during the procedure. This added security is the major advantage of the hand-assisted approach. The major disadvantage is the potential for complications at the incision used for manual access. The complications seen at this site are reminiscent of those seen after open GBP, including major wound infection, dehiscence, and hernia formation.

In a series of hand-assisted laparoscopic GBP procedures from our institution, there was one major wound infection in the hand incision and one instance of postoperative fascial dehiscence. Subsequent study suggested that the hand-assisted procedure did not reduce the incidence of wound-related complications and incisional hernias and that it significantly increased the cost of surgical treatment when compared with open GBP. It appears, therefore, that the primary role of hand-assisted laparoscopic GBP may be in helping surgeons to negotiate the steep learning curve associated with total laparoscopic GBP. Some surgeons, however, have persisted with hand-assisted techniques, and large series have been published.

COMPLICATIONS

The complications observed to date after laparoscopic GBP include the usual problems that occur in some patients after open GBP, including marginal ulcer and stenosis at the gastrojejunal anastomosis necessitating dilatation. On rare occasions, a gastrogastic fistula may lead to a treatment-resistant marginal ulcer. The major advantage of laparoscopic GBP over open GBP is likely to be reduced wound complications (e.g., major wound infection and incisional hernia). We have seen several relatively minor trocar site infections after laparoscopic GBP but none that carried the long wound-care disability characteristic of a major wound infection after open GBP. Intermediate-term weight loss with laparoscopic GBP appears to be identical to that with open GBP.

Postoperative Management

After operation, the obese patient should be kept in the reverse Trendelenburg position and should not be extubated until he or she is fully alert and showing evidence of adequate ventilatory effort [see 8:6 *Mechanical Ventilation*]. In the absence of respiratory insufficiency, most obese patients can

be extubated in the OR or the recovery room and returned to a standard hospital room.

Patients with obstructive SAS may have to be managed with overnight mechanical ventilation in the ICU, particularly if an open bariatric procedure was performed. Patients who were receiving ventilatory support with nasal CPAP before operation should have this treatment reinstituted after operation; monitoring for prolonged apnea should be continued in the ICU or in a stepdown unit with digital oximetry. If apnea occurs, simply waking the patient should correct the problem.

Patients with OHS may require prolonged mechanical ventilation until the pain of breathing resolves, particularly after open procedures. Such patients cannot be expected to manifest normal ABG values, and they should be weaned to their preoperative values—hence the value of obtaining baseline ABG values before operation in these patients. The weaning process may require several days. It is important that these patients remain in the reverse Trendelenburg position to maximize diaphragmatic excursion by reducing the pressure on the chest cavity that may result from the often very large and heavy abdominal cavity. Swan-Ganz catheters, inserted preoperatively in patients with severe OHS, are useful in monitoring postoperative intravascular volume and oxygen delivery status. Excessive diuresis or restriction of fluids should be avoided.

It is extremely important to encourage early postoperative ambulation for the morbidly obese patient. These patients often experience less pain than one might expect, and it is frequently possible to get motivated patients up and walking in the afternoon or early evening after a major abdominal procedure. If the patients have been advised preoperatively of the merits of early postoperative ambulation and know it is for their own welfare, they may be more willing to cooperate.

These basic principles of postoperative management generally apply to laparoscopic cases as well, but with some differences. Unlike patients who have undergone open GBP, those who have undergone laparoscopic GBP usually do not have a nasogastric tube left in place. The bariatric surgical patient may begin to drink small amounts of liquids on postoperative day 1 and may be kept on a liquid diet with liquid protein supplementation for several weeks. Alternatively, many programs advance postoperative patients to a pureed diet with no sugar or concentrated sweets as soon as they can tolerate it. We have found that when patients consume only liquids during the edematous healing phase of the anastomosis, there is less need for urgent dietary counseling during the first few weeks after surgery. Discharge usually takes place between 1 and 3 days after operation. Vitamin administration should be initiated early after operation; chewable tablets may be used if necessary. Thiamine deficiency is very uncommon but can be quite serious if it progresses to the Wernicke-Korsakoff syndrome of neurologic damage. Such deficiency may develop within weeks in patients who are kept on a liquid-only diet without multivitamins but appears to be more common in patients who experience persistent vomiting. Any postoperative bariatric surgical patient with unexplained neurologic symptoms (e.g., visual changes, confusion, sensory changes in the extremities, or gait disturbance) should

be considered for evaluation of potential nutritional causes, including thiamine deficiency and vitamin B₁₂ deficiency.

The basic principles of postoperative management apply to both laparoscopic and open cases.

General Complications of Surgery in the Morbidly Obese Patient

The following are some of the main complications that may be associated with any abdominal operation (open or laparoscopic GBP, VBG, or LAGB) in a severely obese patient.

ABDOMINAL CATASTROPHE

It may be very difficult to recognize an abdominal catastrophe in patients who are very young, very old, or morbidly obese or who are receiving high doses of steroids. For example, the obese patient may present in the ED with a perforated duodenal ulcer or a ruptured diverticulum, complaining of abdominal pain, and yet on abdominal examination have no evidence of peritoneal irritation (i.e., no guarding, tenderness, or rigidity). This situation has been well documented in patients in whom an anastomotic or gastric leak has developed after operation for morbid obesity.⁶² Symptoms include shoulder pain, pelvic or scrotal pain, back pain, tenesmus, urinary frequency, and, of great importance, marked anxiety. Signs of infection (e.g., fever, tachypnea, and tachycardia) may be absent, though tachycardia is often the first sign of a significant problem. Patients with peritonitis often have clinical symptoms and signs suggesting a massive pulmonary embolus: severe tachypnea, tachycardia, and sudden hypotension. Such acute pulmonary failure is probably secondary to sepsis-induced acute respiratory distress syndrome (ARDS). Thus, peritonitis must be suspected in any morbidly obese patient with acute respiratory failure. One advantage of the laparoscopic approach to bariatric surgery is that if there is concern about a possible leak, reexploration can be carried out without the need to reopen a large abdominal incision.

Because a high index of suspicion of peritonitis is required to detect the condition in morbidly obese patients, radiographic contrast studies with water-soluble agents such as diatrizoate meglumine may be indicated even when there are few clinical signs. If a perforated viscus is suspected, exploratory laparoscopy or laparotomy may be necessary despite normal findings on radiographic contrast study.

INTERNAL HERNIA

GBP places patients at risk for internal hernia with a closed-loop obstruction, leading to bowel strangulation. There are three typical locations for these internal hernias: the jejunojejunostomy anastomosis, the opening in the transverse mesocolon through which the retrocolic Roux limb is brought, and the Petersen hernia (located posterior to the Roux limb between the Roux mesentery and the transverse mesocolon). The primary symptom of an internal hernia is periumbilical pain, usually in the form of cramping consistent with visceral colic. These internal hernias may be very difficult to diagnose. Upper GI radiographic series and abdominal CT scans are often normal, providing a false sense of security. The resulting assumption that no problem exists may be devastating for the patient should bowel infarction occur as a consequence of closed-loop obstruction. The plain abdominal

radiograph should always be carefully inspected for abnormal placement or spreading of the staples in the Roux-en-Y anastomosis. The safest course of action in patients with recurrent attacks of cramping periumbilical pain is abdominal surgical exploration. The frequency of this complication seems to have increased with the advent of laparoscopic GBP, presumably because of the difficulty of closing the potential hernia spaces completely. Some attribute the problem to the decreased tendency toward adhesion formation after laparoscopic surgery or to reduction of the intra-abdominal fatty tissue in the mesentery after successful weight loss surgery. We have seen one patient who had a patent mesenteric defect despite an intact suture; the apparent cause of the defect was a dramatic reduction in the mesenteric fat incorporated in the closure.

ACUTE GASTRIC DISTENTION

After GBP, massive gaseous distention occasionally develops in the distal bypassed stomach, sometimes leading to a gastric perforation or disruption of the gastrojejunostomy. The primary symptoms of this complication are hiccups and a bloated sensation reported by the patient. Massive gastric dilatation can lead to severe left shoulder pain and shock. During the era when open GBP was predominant, gastric paralytic ileus was a known cause of this complication, particularly in patients requiring extensive adhesiolysis at the time of the bypass. Currently, with the advent of laparoscopic GBP, the problem is usually secondary to transient edema or to mechanical obstruction at the jejunojejunostomy anastomosis. The diagnosis is made by means of an urgent upright abdominal radiograph, which reveals the markedly dilated and air-filled bypassed stomach. Occasionally, the stomach is filled with fluid, and the diagnosis may be more difficult; in such cases, CT scanning may be helpful. Percutaneous transabdominal skinny-needle decompression can aid in the management of this complication and allow time for tissue edema at the jejunojejunostomy to resolve. If the dilatation recurs or the patient experiences serious difficulty, an emergency laparotomy should be performed, a gastrostomy tube inserted, and the jejunojejunostomy evaluated.

ALTERED INSULIN REQUIREMENTS IN DIABETIC PATIENTS

Patients with type 2 diabetes may require large amounts of insulin for blood glucose control because of significant insulin resistance. It is not unusual, however, to note a complete absence of the requirement for insulin in the immediate postoperative period in morbidly obese patients. Therefore, insulin should be withheld on the morning of operation. In morbidly obese patients who have undergone GBP, there is often a marked reduction in the requirement for insulin throughout the postoperative period and even at discharge, possibly because of increased release of gastric inhibitory peptide (GIP) from the proximal small bowel. Therefore, regular subcutaneous insulin should be administered to GBP patients according to a sliding scale after operation until insulin requirements can be determined. Before discharge, the patient should be taking an appropriate dose of insulin, but afterward, he or she must perform frequent finger-stick blood glucose determinations, given that the need for insulin will decrease progressively with weight loss.

In one study of 23 patients with diabetes mellitus who underwent gastric bariatric operation, the average

requirement for insulin decreased from 74 units/day before operation to 8 units/day after operation.⁶³ Fourteen of the 23 patients were able to discontinue insulin completely, 11 by the time of discharge from the hospital 1 week after operation. These benefits were maintained during long-term follow-up to 39 months and were a result of a major decrease in insulin resistance that was associated with decreased food intake, as well as with weight loss.

Failed Weight Loss and Weight Regain

A postoperative problem that deserves special mention is the risk of failed weight loss or weight regain. This is one of the most difficult problems associated with bariatric surgery and may arise after any gastric procedure for morbid obesity. Patients who have undergone gastroplasty or gastric banding may have difficulty with solid foods and come to exhibit maladaptive eating behavior involving frequent ingestion of high-calorie liquid carbohydrates (a common reason for failure of a bariatric procedure). Conversion to GBP appears to be a successful management strategy for these patients. In a study in which 53 VBG patients were converted to GBP, the average loss of excess weight after VBG was $31 \pm 5\%$; 2 years after conversion to GBP, the average loss of excess weight increased to $67 \pm 2\%$, a value virtually identical to that in the primary GBP group.⁶⁴

Inadequate weight loss is also seen in GBP patients. In some, stomal dilatation eventually develops after the procedure; however, no correlation between stomal size and weight loss has been demonstrated for GBP patients, and reoperation to make the pouch or the stoma smaller has not yielded any benefit over time when the initial procedure has failed.

New techniques for narrowing the dilated gastrojejunostomy stoma endoscopically are currently being tested, but there remains the larger question as to whether such interventions are of any real value for long-term weight control. In a small percentage of patients, the failure of GBP may be attributable to either the loss or the absence of dumping syndrome symptoms, which leads to resumed ingestion of high-calorie sweets or, more commonly, to frequent ingestion of high-fat junk foods (e.g., potato or corn chips, microwave popcorn, and peanut butter crackers) that crumble easily and empty quickly from the pouch, thereby keeping the patient from feeling full. Repeated dietary counseling over a period of years is required to educate patients to eat low-calorie, high-fiber foods (e.g., raw carrots, broccoli, cauliflower, apples, and oranges) that stay in the small gastric pouch longer and provide a sensation of early satiety.

We make clear to patients, well in advance of the operation, that bariatric surgery is designed to provide them with a tool that will assist them in behavior modification and thereby help them help themselves. Obesity can be beaten by surgical treatment, but patients must continue to make good food choices. Patients who begin to ingest more than 1,100 kcal/day often begin to gain weight; even if the weight gain is only 0.5 lb/month, this amounts to 6 lb/year, or 60 lb in 10 years. Bariatric surgical patients may need lifelong nutritional counseling to optimize the results of surgical management of morbid obesity. In addition, appropriate regular physical exercise is an important adjunct to surgical treatment, and patients who comply with exercise treatment not only lose more weight but also are better able to maintain their weight loss. Accordingly, we recommend that patients follow a suitable exercise regimen for the rest of their lives.

Gastric Adenocarcinoma

The incidence of gastric carcinoma exhibits significant geographic variability. The disease is most common in Japan and China, and high rates of occurrence have also been reported in Central and South America, eastern Europe, and parts of the Middle East.¹ In most of the more developed nations, however, gastric carcinoma is relatively uncommon. The overall incidence of this condition has decreased in the past few decades, but gastric carcinoma remains the second leading cause of cancer death worldwide. The reported reductions in gastric cancer mortality appear to be linked to better refrigeration and a concomitant decrease in the intake of salted, pickled, smoked, and chemically preserved foods. An inverse association with the consumption of fresh fruits and vegetables has also been noted.²

Gastric cancer occurs 1.5 to 2.5 times more frequently in males than in females. It is rarely diagnosed before the age of 40, and its incidence peaks in the seventh decade of life. African Americans, Hispanic Americans, and Native Americans are two times more likely to have gastric cancer than white Americans are.³

In the United States in particular, the incidence of stomach cancer has fallen substantially over the past 70 years.⁴ Whereas this disease was once a leading cause of cancer-related death in the United States, it now ranks 13th among major causes. Unfortunately, the decline in incidence has not translated into an improvement in the 5-year survival rate.⁵ Across all races, the 5-year relative survival was 23% for the period extending from 1992 to 1999.³ This result is probably related to the advanced stage at which most patients present. A 2000 study from the National Cancer Data Base found that 55% of patients with gastric cancer presented with locally advanced or metastatic disease.⁶ Resection rates ranged from 40 to 60%, and 5-year survival rates after resection with curative intent were directly related to stage at presentation. For stage IA disease, the survival rate was 78%; for stage IB, 58%; for stage II, 34%; for stage IIIA, 20%; for stage IIIB, 8%; and for stage IV, 7%.

Another relevant change in the epidemiology of gastric cancer is a shift in the distribution of primary lesion sites within the stomach. In the first quarter of the 20th century, two thirds of gastric cancers were located in the antrum and the prepyloric area and only 10% arose in the cardia or the esophagogastric junction. Since the 1970s, however, adenocarcinoma of the proximal stomach has become increasingly common. In one study, the incidence of adenocarcinoma of the gastric cardia rose from 29.1 to 52.2% in the period between 1984 and 1993.⁷ In another study, which included

18,365 gastric cancer patients from Commission on Cancer–approved hospitals, 31% of tumors were found to be in the proximal stomach, compared with only 26% in the distal third.⁸ In the United States, carcinoma of the cardia occurs primarily in whites, with a male-to-female ratio of approximately 2:1. Cancer of the cardia appears to be distinct from adenocarcinoma of the distal esophagus, which frequently arises in the setting of Barrett esophagus.⁹ Associations have also been reported between cancer of the gastric cardia and infection with *Helicobacter pylori* or Epstein-Barr virus.^{10,11}

CLASSIFICATION

Adenocarcinoma of the stomach may be divided into two histologic subtypes, intestinal and diffuse.¹² Each subtype has unique pathologic, epidemiologic, etiologic, and prognostic features. The intestinal (or glandular) subtype usually arises in the distal stomach (often after a long precancerous phase), is more common in elderly patients, and has been closely associated with atrophic gastritis and diets high in nitrates and nitrose compounds.¹³ The characteristic histologic finding is cohesive neoplastic cells that form glandlike tubular structures. The diffuse subtype occurs more frequently in younger patients and has no identifiable precursor lesion. It may develop in any part of the stomach but shows a predilection for the cardia. Cell cohesion is absent; thus, individual cancer cells infiltrate and thicken the stomach wall without forming a discrete ulcer or mass.

In general, the prognosis for the diffuse subtype is worse than that for the intestinal subtype. Whereas intestinal lesions are seen more frequently in regions with a high incidence of gastric cancer, the incidence of diffuse lesions is constant among various populations throughout the world.¹⁴ Accordingly, the overall decline in gastric cancer over the past century has been attributed to a decline in intestinal lesions and to a decline in the incidence of *H. pylori* infection (see below).

RISK FACTORS

Historical studies of specimens obtained during operation or at autopsy suggest that gastric carcinoma, especially of the intestinal subtype, frequently develops in the presence of chronic atrophic gastritis and associated intestinal metaplasia. It has generally been assumed that adenocarcinoma of the distal stomach progresses from chronic gastritis to metaplasia through the teratogenic influence of environmental factors. The most commonly studied environmental factors are the nitrates and nitrose compounds present in high levels in salted, smoked, or pickled foods consumed in areas where gastric cancer is endemic.¹⁵ To date, however, no prospective

studies have conclusively demonstrated that modern refrigeration practices and the subsequent decline in the salting, smoking, and pickling of food have been responsible for the relative decline in intestinal gastric cancer. Furthermore, the intestinal subtype may arise in the absence of metaplasia. Finally, the emergence of chronic infection with *H. pylori* as the dominant risk factor for gastric adenocarcinoma has challenged the paradigm of the atrophic gastritis–intestinal metaplasia–gastric cancer sequence.

Epidemiologic studies across various populations worldwide have consistently demonstrated a strong association between *H. pylori* infection and gastric cancer.¹⁶ Prospective serologic studies have confirmed that persons with evidence of such infection are three to six times more likely to have gastric cancer than persons who are seronegative.¹⁷ Still, only a very small fraction of infected persons develop gastric cancer. It has been estimated that more than half of the world's inhabitants may be infected with *H. pylori*—a number that dwarfs the actual incidence of gastric cancer. What is clear is that *H. pylori* infection of the gastric mucosa leads to a state of chronic active inflammation that lasts for decades. This inflammatory process appears to be modulated by multiple forces, including genetic and environmental factors.¹⁸ Inherited traits may confer susceptibility or resistance to carcinogenesis. Indeed, first-degree relatives of gastric cancer patients have a two to three times higher relative risk of contracting the disease.¹⁹ Gastric irritants may act as promoters, and antioxidants may have a protective effect (which may be part of the reason for the reduced risk of gastric cancer associated with diets rich in fruits and vegetables).²⁰

Unlike intestinal cancers, diffuse cancers appear not to be associated with *H. pylori* infection. Diffuse adenocarcinoma of the stomach is more common in young patients and has no known precursor lesion.⁹ The incidence of genetically associated diffuse cancers is estimated to be in the range of 5 to 10%.¹⁹ Familial cases of diffuse gastric cancer occur at an average age of 38 years and are inherited in an autosomal dominant fashion with 70% penetrance.²¹ Patients with blood group A have a 16 to 20% increased risk of gastric cancer.²²

CLINICAL EVALUATION

In high-risk areas (e.g., Japan), mass screening programs have been successful in identifying early gastric cancer, which is generally amenable to surgical cure.²³ In fact, in some Japanese studies, as many as 40% of newly diagnosed patients had early gastric cancer. Unfortunately, in Western countries, the disease is almost always diagnosed relatively late, when it is locally advanced or metastatic. When it is superficial, gastric cancer typically produces no symptoms. As it progresses, however, a constellation of vague, nonspecific symptoms may develop, including anorexia, fatigue, weight loss, and epigastric discomfort. Dysphagia, early satiety, vomiting, and hematemesis also are seen, albeit rarely; when present, they often indicate advanced disease. Indeed, early gastric cancer has no characteristic physical findings, and many patients are not diagnosed until they present with jaundice, ascites, or a palpable mass, all of which signal incurable disease. Although rare, certain physical examination findings are indicative of metastases, including the Virchow node (left supraclavicular lymph node), Sister Mary Joseph nodule (periumbilical metastasis), Irish node (axillary lymph

node), and Blumer shelf (metastases palpable on a rectal examination in the rectouterine or rectovesical space).

INVESTIGATIVE STUDIES

Until comparatively recently, an upper gastrointestinal (GI) series was often the first diagnostic test ordered to evaluate symptoms related to the upper GI tract. However, even with double-contrast techniques, which allow improved visualization of mucosal detail, false negative rates as high as 25% were reported, especially with small lesions (i.e., 5 to 10 mm).²⁴ Accordingly, in most large series, fiberoptic endoscopy with biopsy has replaced contrast radiography as the primary diagnostic technique.²⁵ Upper GI endoscopy with biopsy has been reported to have a diagnostic accuracy of 95%.²⁰ However, false negatives have been reported, especially in the context of inadequate biopsies. Thus, it is recommended that at least four biopsies be taken from the region of any atypical findings.²⁶

STAGING

Two major classification systems are available for staging gastric cancer. The first is the one used in Japan, where gastric cancer is staged according to the general rules for gastric study in surgery and pathology published by the Japanese Research Society for Gastric Cancer (JSGC).²⁷ This elaborate system focuses on the anatomic involvement of specifically numbered lymph node stations. The second system is the one generally used in Western countries—namely, the familiar tumor-node-metastasis (TNM) system developed by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC) [see Table 1 and Table 2].²⁸ The AJCC/UICC staging system is based on a gastric cancer database and classifies lesions according to the depth to which the primary tumor penetrates the gastric wall, the extent of lymph node involvement, and the presence or absence of distant metastases.

The primary goal in the evaluation of gastric cancer patients is to stratify them into two clinical stage groups: those with locoregional disease (AJCC stages I to III) and those with systemic disease (AJCC stage IV).²⁹ The National Comprehensive Cancer Network (NCCN) has developed consensus guidelines for the clinical evaluation and staging of patients with possible gastric cancer. These guidelines are accessible to any practitioner via the Internet (<http://www.nccn.org/>) and are updated annually. Multidisciplinary evaluation is recommended for all patients. A careful history is obtained and a thorough physical examination is performed, with special attention paid to performance status and to comorbid conditions that might preclude operative intervention. Initial laboratory studies include a complete blood cell count with a platelet count; determination of serum electrolyte, blood urea nitrogen, creatinine, and glucose concentrations; and a liver function panel. Chest radiography is performed, along with computed tomography (CT) of the abdomen and pelvis.

Whereas CT is invaluable for detecting ascites, bulky adenopathy, and significant visceral metastases, its overall accuracy in staging tumors is modest: only 70% for advanced lesions and 44% for early lesions.³⁰ CT assesses lymph node involvement primarily on the basis of node size. Thus, its sensitivity for N1 and N2 disease is low, ranging from 24 to 43%; however, its specificity is high, approaching 100%.

Table 1 American Joint Committee on Cancer TNM Clinical Classification of Gastric Carcinoma, 7th Edition⁹⁶

Distant metastasis (M)	M0 No distant metastasis M1 Distant metastasis

Technical advances, such as spiral (helical) CT with intravenous contrast plus appropriate gastric distention with 600 to 800 mL of water (a negative contrast agent), have allowed modest improvements in overall staging with CT [see Figure 1]. Although improving, CT is still limited in its ability to evaluate peritoneal disease and liver metastases smaller than 5 mm.³¹

Given the limitations of CT, in the absence of obvious metastatic disease, locoregional staging with endoscopic ultrasonography (EUS) is vital for accurately assessing tumor penetration through the gastric wall (T stage) and ascertaining whether regional nodes (N stage) or even mediastinal or

para-aortic lymph nodes may be involved [see Figure 2]. EUS is unique among imaging modalities in its ability to image the gastric wall as a five-layer structure, with each layer correlating with an actual histologic layer.³² The overall accuracy of EUS in determining the extent of infiltration ranges from 67 to 92%.³³ EUS features that suggest lymph node metastasis include a rounded shape, hypoechoic patterns, and a size larger than 1 cm. In one study comparing preoperative findings from EUS with pathologic findings at operation, EUS was 100% sensitive for N0 disease and 66.7% sensitive for N1 disease.³⁴ EUS also allows identification and aspiration of small-volume ascites. If cytologic study of the ascitic fluid so obtained confirms the presence of malignant cells, the patient is considered to have metastatic disease and therefore is not eligible for curative-intent surgery. For all of these reasons, EUS is now widely accepted as superior to conventional CT in the regional staging of gastric cancer.⁹

The ultimate goal of any staging evaluation is to ensure that patients with metastatic disease are not treated with nontherapeutic laparotomy or other local therapies (e.g., radiation therapy), which are generally ineffective against advanced disease. Even small-volume metastatic disease identified on the surface of the liver or the peritoneum at laparotomy is associated with poor survival: in one study, patients with such disease had a life expectancy of only 6 to 9 months.³⁵ In these situations, there is little to be gained from attempts at palliative resection.

Staging laparoscopy has proved to be highly relevant to the evaluation of patients with gastric cancer. In a study from the Memorial Sloan-Kettering Cancer Center (MSKCC), the investigators performed laparoscopic exploration on 110 of 111 patients with newly diagnosed gastric cancer.³⁶ Of these 110 patients, 94% were accurately staged, with a sensitivity of 84% and a specificity of 100%, and 37% were found to have subclinical metastatic disease. Hospital stay was substantially shorter in the 24 patients who underwent diagnostic laparoscopy with biopsy only (average 1.4 days) than in comparable patients who underwent exploratory laparotomy

Figure 1 Shown is a computed tomographic scan of a patient with advanced gastric carcinoma. Water (a negative contrast agent) has been used to distend the stomach. The images were acquired with the patient in the prone position to allow the stomach to fall away from the retroperitoneum and to define the interface between the stomach and pancreas.

without resection (average 6.5 days). Finally, at the time the data were reported, none of the patients who underwent laparoscopy had required palliative surgery. Subsequent single-institution series confirmed the utility of staging laparoscopy, reporting accuracy rates ranging from 95 to 97% and occult M1 disease rates approaching 30%.^{37,38} Taken as a whole, the data are compelling and have led the NCCN to encourage laparoscopic staging strongly, either before or at the time of the planned resection.³⁹

MANAGEMENT

Surgical Therapy

Surgical resection remains the only potentially curative therapy for localized gastric cancer [see Figure 3]. Cure requires removal of all gross and microscopic disease. More specifically, a margin-negative (R0) resection entails wide local excision of the primary tumor with en bloc removal of all associated lymphatic vessels and any local or regional

Figure 2 (a) Shown is an endoscopic ultrasonographic (EUS) image of a T3 gastric neoplasm. (b) EUS reveals the presence of suspicious perigastric (N1) nodes, later confirmed as malignant at operation.

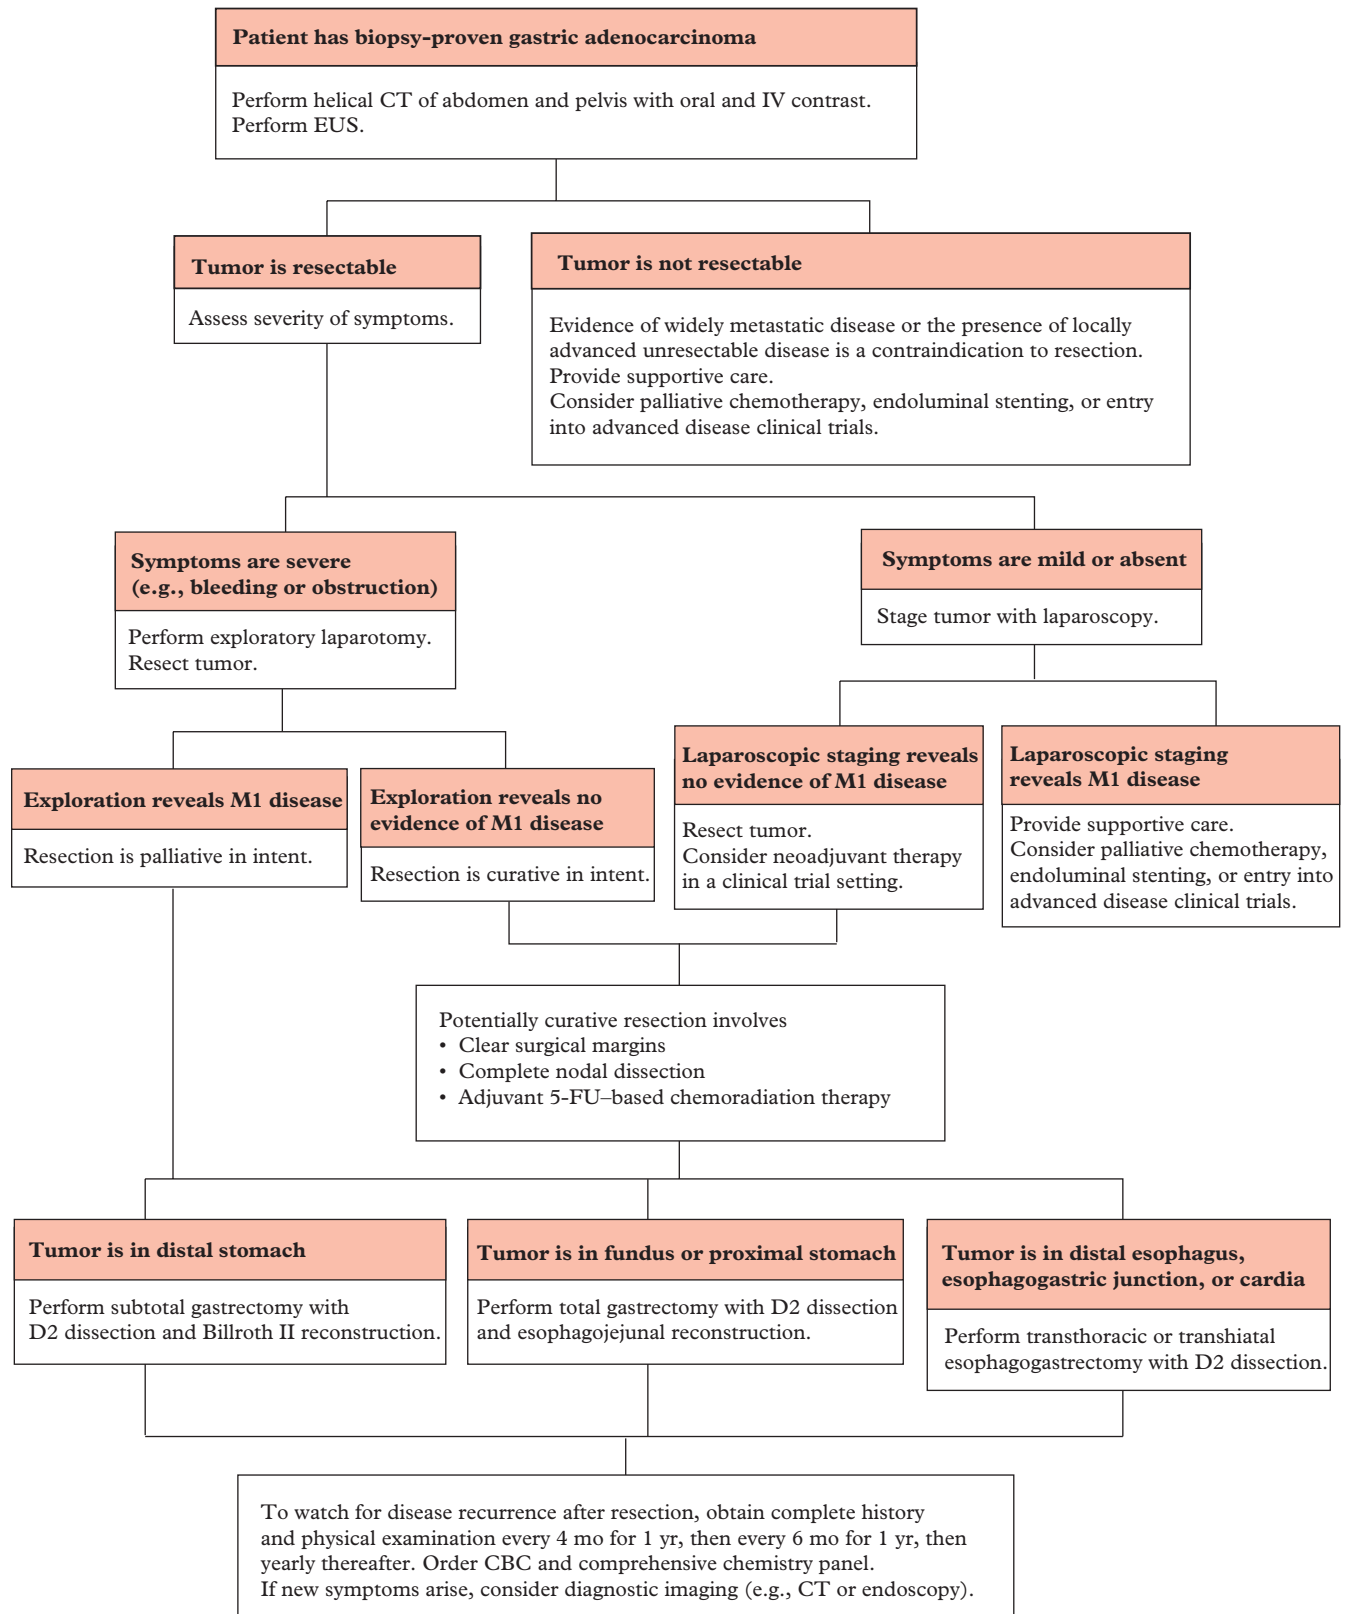

Figure 3 Algorithm illustrating the workup and treatment of a patient with gastric carcinoma. CBC = complete blood cell count; CT = computed tomography; EUS = endoscopic ultrasonography; 5-FU = 5-fluorouracil.

extension of disease. The downside of surgical resection as a sole modality of therapy is that it has a high rate of relapse. Consequently, several areas of surgical treatment of stomach cancer remain subject to controversy. In particular, the extent of gastric resection, the extent of lymph node dissection, the optimal approach to proximal stomach lesions, and the role of splenectomy and adjacent organ resection continue to generate significant debate. Moreover, recent single-center studies have demonstrated the feasibility of laparoscopic resection, although this approach is still investigational and not considered the standard of care in the United States.^{40,41}

Extent of gastric resection R0 resection (i.e., resection of all gross disease with microscopically negative margins) has been shown to have a clear impact on overall survival after potentially curative surgery. In the German Gastric Cancer Study, a prospective multicenter observational trial, the calculated 10-year survival rate in the entire population was 26.3%, compared with 36.1% in patients who underwent an R0 resection.⁴² In a large multi-institution adjuvant therapy trial, 19% of patients underwent an R1 resection (i.e., had resection-line involvement); only 9% of patients with stage I, II, or III disease and resection-line involvement survived beyond 5 years, compared with 27% of those who underwent an R0 resection.⁴³ Given the propensity of tumor for submucosal spreading, many authors consider proximal margins of 5 to 6 cm, with routine frozen-section analysis, to be optimal.^{44,45} A nomogram has been constructed and validated that predicts disease-specific survival, accounting for various clinicopathologic features after an R0 resection for gastric cancer.⁴⁶

In an effort to lower the positive margin rate, some surgeons have proposed that total gastrectomy be considered the operation of choice for all operable gastric cancers. This approach, originally based on historical data from single institutions, has been tested in three clinical trials. In the first trial, elective total gastrectomy was compared with subtotal gastrectomy as curative-intent therapy for adenocarcinoma of the antrum.⁴⁷ Elective total gastrectomy did not increase mortality, but it also did not improve 5-year survival (which was 48% in both treatment arms). In the second trial, patients with antral cancer were randomly assigned to undergo either subtotal gastrectomy or total gastrectomy with extended lymph node dissection (ELND) and en bloc distal pancreatectomy and splenectomy.⁴⁸ Total gastrectomy was associated with increased operative time, greater transfusion requirements, and longer hospital stay; however, median survival was significantly better in the subtotal gastrectomy group (1,511 days versus 922 days). In the third trial, the investigators concluded that subtotal gastrectomy should be the procedure of choice for cancer of the distal half of the stomach, provided that an adequate negative proximal margin can be achieved.⁴⁹ This conclusion was based on their finding that 5-year survival was essentially equivalent in the two groups studied (65.3% in the subtotal gastrectomy group versus 62.4% in the total gastrectomy group).

Options for proximal gastric cancer As noted (see above), adenocarcinoma of the gastric cardia and the esophagogastric junction appears to be clinically distinct from adenocarcinoma of the distal stomach,⁵⁰ and its incidence is

currently escalating across all races and age groups. Accordingly, it is imperative that surgeons understand the surgical options for treatment of proximal gastric cancer.⁵¹

For tumors originating from the distal esophagus, esophagectomy—either transhiatal esophagectomy with a cervical anastomosis or transthoracic (Ivor-Lewis) esophagectomy with a thoracic anastomosis—is clearly the procedure of choice. For tumors of the cardia, it has been suggested that esophagogastrectomy might offer a survival advantage over total gastrectomy with an esophagojejunal anastomosis. This suggestion was evaluated in a study of 1,002 patients with adenocarcinoma of the esophagogastric junction.⁵² The investigators divided tumors into three types on the basis of the location of the tumor center—cancers of the distal esophagus (type I), cancers of the cardia (type II), and cancers of the subcardial fundus (type III)—and analyzed the demographic and long-term survival data. Operative mortality proved to be higher with esophagogastrectomy than with extended total gastrectomy. Furthermore, R0 resection and lymph node status were found to be the dominant prognostic factors influencing survival. Finally, in patients with type II lesions, the pattern of lymphatic spread was primarily to paracardial, lesser curvature, and left gastric node groups. These data, taken together, led the authors to conclude that total gastrectomy is preferable to esophagogastrectomy in this setting if a margin-negative resection can be achieved.

An alternative approach to treating proximal gastric cancer is to perform a proximal subtotal gastrectomy. To date, no prospective studies have compared this method with total gastrectomy or transhiatal esophagogastrectomy for esophagogastric junction tumors, but surgeons from the MSKCC have published their retrospective experience with 98 patients who underwent either total gastrectomy or proximal subtotal gastrectomy for proximal gastric cancer over a 10-year period.⁵³ There were no significant differences between the groups with respect to morbidity, mortality, or 5-year survival in selected patients. It remains to be seen whether such excellent results can be achieved at other centers.

Thus, the evidence at present does not support routine performance of total gastrectomy for lesions of the distal fundus or antrum, provided that histologically negative margins are achievable without compromise of the gastric inlet. Our current practice is to perform a subtotal gastrectomy with Billroth II reconstruction for tumors of the distal stomach, a total gastrectomy with Roux-en-Y esophagojejunostomy for most cancers of the fundus and the proximal stomach, and either a transthoracic esophagogastrectomy or a transhiatal esophagogastrectomy with gastric interposition for tumors of the esophagogastric junction and the cardia.

Extent of lymph node dissection Over the past two decades, few topics in the surgical literature have generated more debate than the optimal extent of regional lymphadenectomy for gastric cancer. In Japan, where radical surgery for gastric cancer is now universally accepted, the JRS GC has codified the extent of lymphatic dissection according to the level of nodes dissected.⁵⁴ A D1 lymph node dissection involves resection of the perigastric lymph nodes along the greater and lesser curvature of the stomach. A D0 dissection is anything less than a D1 dissection. A D2 dissection entails resection of the D1 nodes in addition to nodes along the

common hepatic artery, the left gastric artery, the celiac axis, and the splenic artery. A D3 lymph node dissection adds resection of nodes in the hepatoduodenal ligament and the root of the mesentery. Finally, a D4 resection calls for a D3 dissection plus resection of the retroperitoneal para-aortic and paracolic lymph nodes.⁵⁵ The JRS GC defines a curative operation as a gastric resection that includes lymph nodes one level beyond the level of pathologic nodal involvement. Thus, in Japan, a D2 lymph node dissection is considered the standard resection for even relatively early cancers, and numerous studies have cited the benefits of D3 and even D4 lymphadenectomy for advanced carcinoma.^{56–58}

Western surgeons have been reluctant to embrace radical lymphadenectomy, arguing that it has yet to demonstrate an unequivocal survival advantage in any prospective, randomized trial from a Western institution or cooperative group. Detractors further argue that the survival advantage associated with more radical procedures simply reflects stage migration, a higher incidence of early gastric cancers, and differences in tumor biology and body habitus between Japanese and Western populations and point to the increases in operating time and morbidity that often accompany extended gastric resections. One retrospective review of the tumor registries of over 2,000 hospitals in the United States found that D2 lymph node dissection had no survival advantage over D1 lymph node dissection in terms of either the median survival time or the 5-year survival rate.⁵⁹

Two prospective trials from Western Europe examined this issue further in an effort to evaluate the safety and efficacy of ELND. In the Dutch Gastric Cancer Group trial, 711 patients were randomly assigned to undergo either D1 or D2 lymphadenectomy as part of a potentially curative gastrectomy for biopsy-proven adenocarcinoma.⁶⁰ This trial was unique in its use of extensive quality control measures, which included instruction and operative supervision by an expert gastric cancer surgeon from Japan (who also assisted with the processing and pathologic examination of the surgical specimens). Patients without evidence of disseminated metastases underwent either total gastrectomy or, if 5 cm proximal margins could be obtained, distal gastrectomy. In this study, a D2 lymph node dissection entailed distal pancreatectomy and splenectomy. Both morbidity and mortality were significantly higher in the D2 group than in the D1 group, and D2 dissection conferred no demonstrable survival advantage at a median follow-up of 72 months.

In a trial from the Medical Research Council in the United Kingdom, 400 patients with stage I to IIB disease were randomly assigned to undergo either a D1 or a D2 lymph node dissection.⁶¹ There was no significant difference in overall 5-year survival between the two arms, but multivariable analysis demonstrated that clinical stages II and III, advanced age, male sex, and removal of the pancreas and the spleen were independently associated with poor outcome. The authors concluded that the classic Japanese D2 dissection offered no survival advantage over D1 dissection. However, they hypothesized that D2 dissection with preservation of the distal pancreas and the spleen might lead to decreased morbidity and mortality within the extended resection group and thus potentially to superior outcomes.

Further support for this hypothesis was provided by two nonrandomized trials from specialized centers. The Italian

Gastric Cancer Study Group (IGCSG) completed a phase II multicenter trial designed to evaluate the safety and efficacy of pancreas-preserving D2 lymph node dissection.⁶² Quality control measures included supervision by a surgeon who had studied the technique of D2 lymph node dissection at the National Cancer Center Hospital in Tokyo. At a median follow-up time of 4.38 years, the overall morbidity rate for D2 dissection in the 191 patients enrolled was 20.9% and the in-hospital mortality was 3.1%. The 5-year survival rate among eligible patients was 55%. In a prospective series of 125 patients undergoing standardized D2 lymph node dissection at a single Western center, the investigators reported a mortality of 1.37% and an overall morbidity rate of 33.5%.⁶³ As in the IGCSG study, distal pancreatectomy was avoided in all cases, except when direct extension was suspected on the basis of macroscopic findings (5.5% of cases). Overall 5- and 10-year survival rates for this highly selected cohort were 52.3% and 40%, respectively. These studies suggest that D2 lymph node dissection may be safely performed in Western centers when accompanied by careful selection of patients, strict standardization of technique, and a strategy of pancreatic preservation.

Current AJCC guidelines state that pathologic examination of at least 15 lymph nodes is required for adequate staging.²⁸ Specifically, examination of at least 15 nodes is required to confidently deem a patient free of nodal metastases. However, multiple studies have demonstrated inadequate nodal assessment that is somewhat related to hospital type.⁶⁴ In an effort to confirm the benefit of this staging system, investigators from the MSKCC reviewed their experience with 1,038 patients who underwent R0 resection for gastric cancer.⁶⁵ The location of positive lymph nodes (within 3 cm of the primary tumor versus more than 3 cm away) did not significantly affect median survival; however, the number of positive lymph nodes had a profound effect on survival. Furthermore, in cases in which at least 15 nodes were examined (27% of the total), the median survival for patients with metastasis in one to six regional lymph nodes, metastasis in seven to 15 regional lymph nodes, and metastasis in more than 15 regional lymph nodes was significantly longer than the median survival reported in cases in which 14 or fewer nodes were resected with the specimens. These findings are consistent with published data from our own institution (Northwestern University Feinberg School of Medicine), which indicate that the number of positive lymph nodes is a highly significant predictor of survival.⁶⁶ In our series of 110 patients, those with seven or more positive lymph nodes had a median disease-free survival (DFS) of 17.6 months, whereas those with six or fewer positive nodes had a median DFS of 44 months. Data from other centers support this view as well.

It is our current practice to perform a D2 lymph node dissection with resection of all perigastric lymph nodes along the greater and lesser curvatures of the stomach, as well as those along the common hepatic artery, the left gastric artery, the celiac axis, and the splenic artery. We make every attempt to preserve the tail of the pancreas and spleen, with multivisceral resection reserved for cases of overt direct extension of malignant disease in the absence of disseminated metastasis. This strategy should provide adequate staging in terms of the AJCC guidelines, minimize morbidity, and possibly confer a

survival advantage on certain patient subgroups, as suggested by the results of the trials mentioned.

Role of splenectomy Routine splenectomy has been proposed as a means of facilitating clearance of metastatic nodes along the splenic artery and in the splenic hilum, but there is little evidence to support this practice in the treatment of proximal gastric cancers. Indeed, numerous studies have documented the deleterious effect of splenectomy when it is performed as part of an extended gastric resection.

In a retrospective study of 392 patients who underwent curative gastrectomy at a high-volume cancer center, the impact of splenectomy on survival and postoperative morbidity was evaluated.⁶⁷ Splenectomy was not predictive of death on multivariable analysis, but complications were far more frequent in patients who underwent splenectomy as part of surgical treatment than in those who did not (45% versus 21%). Specifically, the incidence of infectious complications was far higher in the splenectomy group than in the nonsplenectomy group (75% versus 47%).

In a review of data from an American College of Surgeons Pattern of Care Study, the investigators reported that the operative mortality was 9.8% in patients who underwent splenectomy during gastric resection, compared with 8.6% for those who did not.⁶⁸ More significantly, the 5-year observed survival rate was 20.9% in the splenectomy group, compared with 31% in the nonsplenectomy group.

In a randomized, prospective trial, early and late results of total gastrectomy alone were compared with those of total gastrectomy plus splenectomy in patients being treated for cancers of the upper third of the stomach.⁶⁹ All patients underwent a D2 lymph node dissection. The operative mortalities and the 5-year survival rates were similar in the two groups, but the splenectomy group had more infectious complications. Specifically, the splenectomy group had higher incidences of pulmonary complications, postoperative fever higher than 38°C (100.4°F), and subphrenic abscess formation. We agree with the conclusions of the authors of this study: routine splenectomy does not increase survival and should be reserved for situations in which the gastric tumor directly invades the splenic hilum or there is evidence of gross nodal metastases along the splenic artery.

Nonsurgical Therapy

Adjuvant therapy As noted (see above), the majority of patients who present with gastric carcinoma and undergo potentially curative surgical treatment will experience locoregional failure, distant metastasis, or both and will succumb to their disease. Accordingly, numerous adjuvant approaches—including chemotherapy, radiotherapy, chemoradiation, immunochemotherapy, and intraperitoneal chemotherapy—have been tried in gastric cancer patients with the aim of improving overall survival and DFS. The results, for the most part, have been disappointing.

The results from prospective, randomized, controlled trials of adjuvant radiation therapy in this setting have failed to establish a survival benefit. In a multi-institutional trial from 1994, patients were randomly assigned to undergo surgery alone, surgery plus adjuvant radiation, or surgery plus adjuvant multiagent chemotherapy.⁷⁰ There was no significant

benefit to either adjuvant regimen: overall 5-year survival was 20% for surgery alone, compared with 12% for surgery plus radiation therapy and 19% for surgery plus chemotherapy.

The results from trials of chemotherapy alone have been equally unsatisfactory. Because of the established inefficacy of single-agent 5-fluorouracil (5-FU) therapy, combination chemotherapy regimens have been employed. Such regimens have included nitrosourea compounds, mitomycin C, anthracyclines, and members of the cisplatin family.²³ In a meta-analysis of 13 trials comparing adjuvant chemotherapy with observation in non-Asian countries, the odds ratio for death in the treated group was 0.8, corresponding to a relative risk of 0.94.⁷¹ This result did not, however, reflect a statistically significant improvement. Most oncologists have now abandoned the use of chemotherapy by itself in the adjuvant setting.

In an effort to derive greater therapeutic benefit than can be achieved with either radiation therapy or chemotherapy alone, combination chemoradiation therapy has been used in the adjuvant setting. In Intergroup Trial 0116, 556 patients who had undergone R0 resection of adenocarcinoma of the stomach or the esophagogastric junction were randomly assigned to treatment with either surgery alone or surgery plus postoperative chemoradiotherapy.⁷² Patients with tumors ranging from stage IB to stage IVM0 were included; the majority had T3 tumors and node-positive disease. The therapeutic regimen consisted of 5-FU and leucovorin therapy administered concomitantly with 45 Gy of external-beam irradiation over a period of 5 weeks. Median overall survival in the surgery-only group was 27 months, compared with 36 months in the surgery-chemoradiation group. In addition, the 3-year survival rate was 41% in the surgery-only group, compared with 50% in the chemoradiotherapy group. The hazard ratio for death in the surgery-only group compared with the chemotherapy group was 1.35.

In the United States, the results of Intergroup Trial 0116 have led to the acceptance of combined chemoradiation therapy as standard adjuvant therapy for patients who have undergone curative-intent resection of gastric cancer. Nonetheless, numerous criticisms of this trial have been expressed. Specifically, a review of the operative and pathology reports of 453 of the patients revealed a lack of surgical standardization.⁷³ When the extent of lymphadenectomy was categorized, the majority (54.2%) of the patients were found to have undergone a D0 resection; 38.1% underwent a D1 resection, and only 7.5% underwent a D2 or D3 lymph node dissection. These findings suggest that the main effect of the chemoradiation therapy may have been simply to compensate for inadequate surgery. This suggestion is supported by the observation that the number of patients with local and regional recurrences was higher in the surgery-only group (178 versus 101), whereas the number of patients with distant failure was slightly higher in the adjuvant therapy arm (40 versus 32). Furthermore, when the Maruyama Index of Unresected Disease (a computer model developed for accurate prediction of nodal station involvement in gastric cancer) was applied to the 556 patients eligible for the Intergroup trial, the median Maruyama Index was 70.⁷⁴ This value was far above the level considered to represent optimal surgical therapy (i.e., Maruyama Index < 5) and led the authors to conclude that the vast majority of patients in the trial had been surgically undertreated.

Currently, physicians, especially in Europe, generally avoid adjuvant therapy after R0 resection of gastric cancer, except under the auspices of a clinical trial.⁹ The Radiation Therapy Oncology Group has initiated a phase II trial of adjuvant chemoradiotherapy using 45 Gy of external beam radiation therapy with cisplatin and paclitaxel, with or without 5-FU. If promising results are found, a phase III trial will follow. It is hoped that ongoing trials will shed further light on this complex management issue.

Neoadjuvant therapy As a response to the disappointing results of adjuvant therapy and the inability of many patients to regain adequate performance status after radical gastric surgery to undergo systemic therapy, neoadjuvant protocols have been proposed.⁷⁵ The theoretical benefits of a neoadjuvant treatment strategy include treatment-induced tumor downstaging, which may enhance resectability, and early administration of systemic therapy, which allows almost all patients to receive and complete the prescribed treatment. Furthermore, because treatment is administered when measurable disease is present, the response to therapy may be assessed and continued only in patients who are likely to benefit. Finally, patients found to have rapidly progressive disease during preoperative chemotherapy may be spared having to undergo a nontherapeutic gastrectomy.⁷⁶

In a report of three phase II trials from the M.D. Anderson Cancer Center encompassing 83 patients who received neoadjuvant chemotherapy before planned surgical resection, the clinical response rates ranged from 24 to 38%, with three patients (4%) exhibiting a complete pathologic response.⁷⁶ Sixty-one patients (73%) were able to undergo a curative-intent resection, and the response to chemotherapy was the only significant predictor of survival on multivariable analysis.

Preoperative chemoradiation therapy has also been shown to be feasible in phase II trials. In a 2001 trial that included 23 patients, 96% of the study population received combined modality therapy.⁷⁵ Nineteen patients (83%) were able to undergo surgical resection with D2 lymphadenectomy; four patients (17%) had progressive disease and did not undergo resection. Morbidity and death rates were acceptable (32% and 5%, respectively), and 11% of patients exhibited complete pathologic responses. Overall, 63% of patients showed pathologic evidence of a significant treatment effect.

Newer neoadjuvant strategies employ multiagent induction chemotherapy followed by chemoradiotherapy and planned gastric resection in patients with locally advanced but potentially resectable gastric cancer.⁷³ Based on the results of the Intergroup Trial 0116, the Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial was developed to determine whether neoadjuvant epirubicin, cisplatin, and infused fluorouracil (ECF) resulted in improved outcomes compared with surgery alone.⁷⁷ Postoperative morbidity and mortality were comparable between the two groups, but overall survival (5-year survival 36% versus 23%; hazard ratio 0.75) and progression-free survival (hazard ratio 0.66) were improved in patients who received neoadjuvant ECF. Thus, the NCCN now recommends neoadjuvant therapy for locally advanced (T3 or node positive based on EUS) gastric cancer.

FOLLOW-UP AND MANAGEMENT OF RECURRENT DISEASE

Even after gross resection of all disease with microscopically negative margins (R0 resection), recurrence of gastric carcinoma is common. Adenocarcinoma of the stomach may spread through direct extension, via lymphatic channels to regional and distant lymph nodes, or via the bloodstream to distant sites. Furthermore, once tumors have penetrated the serosa (T3), peritoneal metastasis becomes a possibility. Through autopsy series and clinical studies, certain definite patterns of locoregional failure and distant metastasis have been established. Locoregional recurrences are common in the gastric bed and the adjacent lymph nodes. Clinical and reoperative evaluation have documented recurrent disease at the anastomosis, in the retroperitoneum, or in the regional lymph nodes in 3 to 69% of patients; the incidence of recurrence may vary, depending on whether the patients had received adjuvant therapy.²³ One autopsy series documented a locoregional recurrence rate of 94% in patients treated with surgery alone. The peritoneum is ultimately involved in 17 to 50% of all patients. The most common sites of visceral metastases are the liver and the lungs.

In view of the high recurrence rates, all patients who have undergone resection should be seen for routine surveillance examinations. Currently, the NCCN recommends that a complete history and physical examination be conducted every 3 to 6 months for 1 to 3 years, every 6 months for 3 to 5 years, and then annually thereafter.³⁹ A complete blood count, serum electrolyte concentrations, imaging studies (e.g., CT), and endoscopy should be done if clinically indicated, usually in response to new symptoms. In addition, long-term vitamin B₁₂ supplementation should be initiated for patients who have undergone a proximal or subtotal gastrectomy.

Nonadenocarcinomatous Gastric Malignancies

GASTRIC LYMPHOMA

Gastric lymphoma is the second most common malignancy of the stomach, accounting for 2 to 9% of gastric tumors in the United States. Lymphomas of the stomach are of the non-Hodgkin type. The stomach is the most common site of extranodal involvement of non-Hodgkin lymphoma (NHL) and accounts for nearly 50% of all such cases.⁷⁸

Clinical Evaluation

The presenting symptoms of gastric lymphoma, like those of gastric adenocarcinoma, are nonspecific and include loss of appetite, weight loss, vomiting, and bleeding. B symptoms (e.g., fever and night sweats) are relatively rare: in one multicenter trial concerned with primary gastric lymphoma, they occurred in fewer than 12% of patients enrolled.⁷⁹ Risk factors for gastric lymphoma include *H. pylori* infection, immunosuppression after solid-organ transplantation, celiac disease, inflammatory bowel disease, and HIV infection.⁸⁰

Investigative Studies

The diagnosis is most frequently established by means of endoscopy with biopsy. Staging studies include a comprehensive blood count, a lactate dehydrogenase level, and a comprehensive chemistry panel; CT of the chest, abdomen, and pelvis; and, often, a bone marrow biopsy. All pathology slides should be reviewed by an experienced hematopathologist.⁸¹

Staging and Prognosis

Numerous staging systems have been employed to stage NHL of the GI tract. Of these, the one most commonly applied is a modification of the Ann Arbor staging system for lymphoma.⁸⁰ For surgeons, the most important determination is often whether the NHL (1) is confined to the stomach and the perigastric nodes (stage I and II disease), (2) involves other intra-abdominal nodes and organs (stage III), or (3) extends outside the abdomen (stage IV).⁸²

Management

Over the past decade, the management of patients with gastric lymphoma has undergone significant changes. Generally, there has been a shift away from surgical management, even in relatively localized cases (stages I and II).⁸³ This shift is the result not only of the documented success of chemotherapy alone for more advanced cases (stages III and IV) but also of a better understanding of the etiology of gastric lymphoma.⁸⁴ Approximately 45% of all gastric lymphomas are low-grade mucosa-associated lymphoid tissue (MALT) lymphomas.⁷⁹ The gastric mucosa is normally devoid of lymphoid tissue. It is hypothesized that MALT develops in the stomach in response to chronic *H. pylori* infection.⁸⁵

Nonsurgical therapy Low-grade MALT lymphoma usually presents as stage I or II disease and has an indolent course. Since 1993, when regression of low-grade MALT lymphoma after eradication of *H. pylori* was first reported, numerous trials have documented the efficacy of anti-*H. pylori* therapy, with complete remission rates ranging from 50 to 100%.⁷⁹ In the German MALT Lymphoma Study, the complete remission rate was 81%; 9% of patients exhibited partial responses, and 10% showed no response.⁸⁶ Low-grade lymphomas that are more advanced or do not regress with antibiotic therapy may be treated with combinations of *H. pylori* eradication, radiation, and/or combination chemotherapy.⁸⁷ For localized persistent disease, modest doses of radiation, on the order of 30 Gy, may be employed. When chemotherapy is required, multiagent regimens, such as cyclophosphamide-vincristine (Oncovin)-prednisolone (COP), are often used.

Approximately 55% of gastric lymphomas are high-grade lesions, which can occur with or without a low-grade MALT component.⁷⁹ These lymphomas are treated with chemotherapy and radiation therapy according to the extent of the disease. The cyclophosphamide-doxorubicin-vincristine (Oncovin)-prednisolone (CHOP) regimen is the one most frequently employed. In some studies, the anti-CD20 monoclonal antibody rituximab has been either added to standard therapy or used alone, with encouraging results.⁸⁸

Surgical therapy Surgical resection, once thought to be essential for the diagnosis, staging, and treatment of early-stage gastric lymphoma, now is used mainly in patients who experience bleeding or perforation. In the German Multicenter Study Group trial, 185 patients with stage I or II gastric lymphoma were treated either with gastrectomy followed by radiation or (in the case of high-grade lesions) chemotherapy plus radiation or with chemotherapy and radiotherapy alone.⁷⁹ There was no significant difference in

survival between the group receiving surgical treatment and the group receiving nonoperative therapy: overall 5-year survival rates were 82.5 and 84%, respectively. There were no perforations and only one hemorrhage (in a patient treated with chemotherapy alone). Similarly, in a single-institution, prospective, randomized trial comparing chemotherapy alone with chemotherapy plus surgery for stage I and II lymphoma, there were no instances of perforation and only three instances of GI bleeding in the chemotherapy group, compared with two bleeding episodes in the surgery plus chemotherapy group.⁸³

Currently, patients with early-stage high-grade gastric lymphomas are treated primarily with chemotherapy or radiation therapy; only rarely do they require surgical intervention for complications encountered during therapy. Patients with locally advanced (stage III) or disseminated (stage IV) gastric lymphoma are clearly best treated with chemotherapy, with or without radiation. Occasionally, surgery is indicated in such patients to treat residual disease confined to the stomach or to palliate bleeding or obstruction that does not resolve with nonoperative therapy. Primary surgical therapy is to be avoided in these patients because of the significant risk of complications and the delay in initiating systemic therapy.

GASTROINTESTINAL STROMAL TUMOR

Gastrointestinal stromal tumor (GIST), although relatively rare in absolute terms, is the most common sarcoma of the GI tract,⁸⁹ with approximately 6,000 cases reported each year in the United States alone. The stomach is the most common site of involvement, accounting for 60 to 70% of cases⁹⁰; the small intestine (25%), the rectum (5%), the esophagus (2%), and a variety of other locations account for the remainder. On the basis of their appearance on light microscopy, GISTs were once thought to be of smooth muscle origin, and most were classified as leiomyosarcomas.⁹¹ Thus, extended gastric resection, often including contiguous organs, was advised. Recurrence developed after R0 resection in approximately 50% of cases.⁹² With the advent of immunohistochemistry and electron microscopy, it became clear that GIST has both smooth muscle and neural elements, and the cell of origin is now believed to be a precursor of the interstitial cells of Cajal, an intestinal pacemaker cell.⁹³ The diagnosis of GIST is secured by immunohistochemical staining for the tyrosine kinase receptor KIT (CD 117), which highlights the presence of interstitial cells of Cajal. More than 95% of GISTs exhibit unequivocal staining for KIT.⁹⁰ Approximately two thirds of GISTs also express CD34. Histologically, these tumors may exhibit a spindle cell pattern, an epithelioid pattern, or a mixed subtype.

Clinical Evaluation

The median age of incidence is 63 years, and tumors are generally between 0.5 and 44 cm in diameter at the time of diagnosis (median diameter 6 cm).⁹⁰ Mass-related symptoms (e.g., abdominal pain, bloating, and early satiety) may be present. Melena or anemia from overlying mucosal ulceration may be present as well. A small subset of patients have peritonitis as a consequence of tumor rupture and subsequent hemorrhage. Finally, many GISTs are discovered incidentally during operation, abdominal imaging, or endoscopy.

Investigative Studies

When a GIST is suspected, abdominal and pelvic imaging with either CT or magnetic resonance imaging (MRI) is indicated. Chest imaging is performed as well. Endoscopy, with or without EUS, may occasionally help with surgical planning, but because of the infrequency of mucosal involvement, it is rarely diagnostic.⁹⁴ Surgical consultation should be obtained to determine whether the lesion can be resected. If the tumor is resectable, biopsy should not be performed, because of the risk of tumor rupture and intra-abdominal dissemination. Biopsy may be required, however, if the patient has widespread disease or may be enrolling in a trial of neoadjuvant therapy. In such cases, biopsy may be performed percutaneously or at the time of EUS.

Staging and Prognosis

Although the majority of gastric GISTs have a benign course, a wide spectrum of biologic behavior has been observed. Of the prognostic factors examined to date, tumor size and mitotic rate appear to be the most valuable. If the tumor is less than 2 cm in diameter and the mitotic count is lower than five per high-power field (HPF), the risk of an aggressive disease course is considered to be very low. Conversely, if the tumor is larger than 10 cm, if the mitotic count is higher than 10/HPF, or if the tumor is larger than 5 cm with a mitotic count higher than 5/HPF, the risk of aggressive clinical behavior is considered to be high. For all other tumors, the risk of aggressive disease is considered to be intermediate.⁹⁰ The site of the primary tumor has also been shown to be important, with gastric GISTs having a better prognosis compared with small bowel GISTs of comparable size and mitotic rate.⁹⁵ In addition, the most recent version of the AJCC Cancer Staging Manual (7th Edition) has an added staging system for GISTs (*Table 3 and Table 4*).⁹⁶

Management

Surgical therapy The role of surgery in the treatment of a GIST is to resect the tumor with grossly negative margins and an intact pseudocapsule. Lymph node involvement is rare with GISTs; thus, no effort is made to perform ELND. The tumor must be handled with care to prevent intra-abdominal rupture. Formal gastric resection is rarely required: as a rule, it is indicated only for lesions in close proximity to the pylorus or the esophagogastric junction. The NCCN has

Table 3 American Joint Committee on Cancer TNM Clinical Classification of Gastrointestinal Stromal Tumors, 7th Edition⁹⁶

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor 2 cm or less
	T2	Tumor 2–5 cm
	T3	Tumor 5–10 cm
Regional lymph nodes (N)	T4	Tumor > 10 cm in greatest diameter
	NX	Regional lymph node(s) cannot be assessed
	N0	No regional lymph node metastasis
Distant metastasis (M)	N1	Regional lymph node metastasis
	M0	No distant metastasis
	M1	Distant metastasis

Table 4 American Joint Committee on Cancer Staging of Gastric and Small Bowel GISTs, 7th Edition⁹⁶

Stage	Tumor	Node	Metastasis	Mitotic Rate
Gastric				
IA	T1, T2	N0	M0	Low
IB	T3	N0	M0	Low
II	T1 T3 T4	N0	M0	High High Low
IIIA	T3	N1	M0	High

GIST = gastrointestinal stromal tumor.

guidelines updated annually specifically for the management of GISTs.⁹⁷

Nonsurgical therapy If the tumor has metastasized or has advanced locally to the point where surgical therapy would result in excessive morbidity, the patient is treated with the tyrosine kinase inhibitor imatinib mesylate. Imatinib is a selective inhibitor of a family of protein kinases that includes the KIT receptor tyrosine kinase, which is expressed in the majority of GISTs. Originally indicated for the treatment of chronic myelocytic leukemia, imatinib was approved for the treatment of KIT-positive GIST in 2002, when phase II clinical trials documented sustained objective responses in a majority of patients with advanced unresectable or metastatic GIST.⁹⁸ Patients with borderline resectable lesions should be treated with imatinib until they exhibit a maximal response as documented by CT and positron emission tomography (PET); surgery may then be undertaken to resect any residual foci of disease. Similarly, although patients with metastatic disease are unlikely to manifest a complete response to imatinib therapy, they should be periodically reevaluated and considered for resection should surgical treatment become technically feasible.⁹⁴

In 2009, the results of the American College of Surgeons Oncology Group (ACOSOG) phase III trial (Z9001) were reported. After resection of intermediate-risk GIST, patients were randomized to treatment with 1 year of imatinib (400 mg/day) versus placebo. Adjuvant imatinib was well tolerated. After a median follow-up of 19.7 months, patients treated with imatinib had a considerably better recurrence-free survival compared with the placebo group (98% versus 83%, $p < .0001$; hazard ratio 0.35). After resection of a

GIST, adjuvant imatinib is recommended for patients with moderate-to-high risk of recurrence.

GASTRIC CARCINOID

Gastric carcinoid tumors are rare, but this incidence is increasing. These tumors now account for approximately 10% of all GI carcinoids and 2% of all gastric tumors.^{99–101} The median age at diagnosis is 64, and the tumors are somewhat more common in women than in men.

Clinical Evaluation and Investigative Studies

Gastric carcinoid tumors are often discovered during endoscopic examination of patients experiencing chronic abdominal pain; patients may also complain of vomiting and diarrhea. These tumors are rarely associated with symptoms of the carcinoid syndrome. Diagnosis is usually confirmed by endoscopic biopsy, and EUS is helpful in determining the extent of gastric wall penetration and the degree of regional lymph node involvement.

Gastric carcinoid tumors have been divided into three types, primarily on the basis of their association (or lack thereof) with hypergastrinemia. Type I tumors are associated with chronic atrophic gastritis, are generally small (< 1 cm), and are often multiple and polypoid. They grow slowly and only rarely metastasize to regional nodes or distant sites. Type II tumors are associated with the Zollinger-Ellison syndrome and multiple endocrine neoplasia type I and, like type I tumors, are usually small and multiple. They also grow slowly but are more likely to metastasize than type I gastric carcinoids are. Type III (sporadic) gastric carcinoid tumors are the most biologically aggressive type. They are often large (> 1 cm) at the time of diagnosis and are not associated with hypergastrinemia. Type III lesions frequently metastasize to regional nodes (54%) or the liver (24%).⁹⁹

Management

For patients with small, solitary type I tumors, endoscopic polypectomy or open resection via gastrotomy (local excision) is the procedure of choice. For patients with multiple or recurrent tumors, antrectomy is indicated to remove the source of the hypergastrinemia. For patients with type II lesions, treatment is similar to that for patients with type I lesions, with the extent of gastric resection determined by the size and number of lesions. For patients with type III lesions, however, either distal or total gastrectomy with ELND is required.¹⁰² All patients undergoing a less than total gastrectomy should be followed with serial endoscopy at regular intervals.¹⁰³

Small Bowel Malignancies

Malignant tumors of the small intestine are rare, accounting for fewer than 5% of all GI tract malignancies. In the United States, approximately 6,000 new cases of small bowel cancer are reported each year.³ The majority of small bowel malignancies are carcinoid tumors, adenocarcinomas, or lymphomas,¹⁰⁴ although GISTs are being noted with increasing frequency in the small intestine. Although adenocarcinomas had traditionally been the most common tumor of the small bowel, a recent report from our group has shown that the incidence of carcinoid tumors has increased over the past

20 years and carcinoids are now the most common tumor of the small intestine.¹⁰⁵ Treatment of lymphomas, carcinoid tumors, and GISTs in the small bowel is nearly identical to treatment of the same lesions in the stomach [see Nonadenocarcinomatous Gastric Malignancies, *above*] and thus are not covered further in this chapter. Our focus here is on the presentation, diagnosis, and treatment of adenocarcinoma of the small bowel (*Table 5 and Table 6*).

CLINICAL EVALUATION

Between 46 and 55% of small bowel adenocarcinomas occur in the duodenum and approximately 13% occur in the ileum.^{97,98,104–106} Patients frequently present with nausea, vomiting, abdominal pain, weight loss, and GI bleeding; occasionally, they present with iron deficiency anemia or a positive fecal occult blood test result. In rare cases, small bowel obstruction, often with the tumor serving as a lead point for intussusception, is the first manifestation of the disease.¹⁰⁶

INVESTIGATIVE STUDIES

When an adenocarcinoma is located in the duodenum, the diagnosis is often made by means of esophagogastroduodenoscopy (EGD). Lesions within the first 100 cm of the small bowel may be evaluated with push enteroscopy. When the adenocarcinoma is situated elsewhere in the small bowel, it is localized with small bowel radiographs. Some authors consider enteroclysis to be superior to the more commonly used small bowel follow-through in this setting in that enteroclysis is better able to demonstrate fine mucosal detail.¹⁰⁷ In experienced hands, enteroclysis may therefore be more sensitive.¹⁰⁸ Some lesions are identified when CT or MRI is performed to evaluate complaints of abdominal pain. Furthermore, abdominal imaging may yield complementary staging information (e.g., the presence of regional adenopathy or metastatic disease). One new method for the identification of small bowel tumors is wireless capsule endoscopy.¹⁰⁹ This minimally invasive technique may be particularly useful in identifying small lesions in the distal jejunum and ileum that cannot be identified radiographically.

MANAGEMENT

Aggressive surgical resection remains the cornerstone of therapy for adenocarcinoma of the small intestine.¹¹⁰ For periampullary lesions, pancreaticoduodenectomy is typically required to achieve a margin-negative resection. For lesions in the distal duodenum, a segmental sleeve resection with a duodenojejunostomy is appropriate. For lesions in the jejunum or the ileum, segmental resection may be performed with a wide mesenteric resection to encompass potentially involved regional lymph nodes. Contiguous organs are resected en bloc as necessary.⁹⁹

Because the presenting signs and symptoms are often vague and nonspecific, diagnosis is often delayed. In one series, only six (11%) of the 53 patients were suspected of having a small bowel tumor at admission.¹¹⁰ In a retrospective review of patients with small bowel tumors treated at our institution, the mean duration of symptoms before surgical management was 110 months, and more than 50% of the patients were found to have stage III or IV disease.¹¹¹ In our work with the National Cancer Data Base, we found that only 24% of patients presented with metastatic disease.¹⁰⁵

Table 5 American Joint Committee of Cancer TNM Clinical Classification of Small Bowel Carcinoma, 7th Edition⁹⁶

Primary tumor (T)	TX Primary tumor cannot be assessed T0 No evidence of primary tumor Tis Carcinoma in situ T1a Tumor invades lamina propria T1b Tumor invades submucosa T2 Tumor invades muscularis propria T3 Tumor penetrates the muscularis propria into the subserosa or into the nonperitonealized perimuscular tissue (mesentery or retroperitoneum) with extension of 2 cm or less T4 Tumor perforates the visceral peritoneum or directly invades other organs or structures (includes other loops of small intestine, mesentery, or retroperitoneum > 2 cm and abdominal wall by way of serosa; for duodenum only, invasion of pancreas or bile duct)
Regional lymph nodes (N)	NX Regional lymph node(s) cannot be assessed N0 No regional lymph node metastasis N1 Metastasis in 1–3 regional lymph nodes N2 Metastasis in 4 or more regional lymph nodes
Distant metastasis (M)	M0 No distant metastasis M1 Distant metastasis

Table 6 American Joint Committee on Cancer Staging of Small Bowel Carcinoma, 7th Edition⁹⁶

Stage	Tumor	Node	Metastasis
0	Tis	N0	M0
I	T1, T2	N0	M0
IIA	T3	N0	M0
IIB	T4	N0	M0
IIIA	Any T	N1	M0
IIIB	Any T	N2	M0
IV	Any T	Any N	M1

The 5-year survival rate continues to be low (24 to 37%).^{105,111–113} Significant predictors of good overall survival include location in the jejunum, complete (R0) resection, low-grade tumors, and low AJCC tumor stage.^{105,111–113} The available evidence indicates that all patients with small bowel neoplasms should be offered an oncologically sound surgical resection. In one series, curative (R0) resection was accomplished in 51% of cases.¹¹³ No prospective data are available regarding adjuvant therapy, but the treatments and results for colon adenocarcinoma are often extrapolated to small bowel adenocarcinomas.

Financial Disclosures: None Reported

9 TUMORS OF THE PANCREAS, BILIARY TRACT, AND LIVER

Steven M. Strasberg, MD, FACS, FRCS(C), FRCS(Ed), and David C. Linehan, MD, FACS

Several different types of tumors affect the pancreas, the biliary tree, and the liver. Each year, hundreds of articles are published regarding pancreatic, biliary, and hepatic cancers. Accordingly, this chapter concentrates on essential principles. In particular, it focuses on common malignant tumors, addressing benign tumors and uncommon tumors only insofar as they are important in differential diagnosis.

When a patient presents with an apparent cancer of the pancreas, the biliary tree, or the liver, the surgeon must attempt to answer the following three important questions:

1. What is the diagnosis?
2. What is the surgical stage of the disease—that is, is the tumor resectable?
3. What is the operative rationale that will encompass the disease and produce a margin-free resection (and, for pancreatobiliary cancers, an N1 resection)?

These questions form the underpinning for the process of investigation and management. In what follows, we describe our approach to each of the cancers in these terms.

Pancreatic Cancer

DUCTAL ADENOCARCINOMA

Ductal Adenocarcinoma of the Head of the Pancreas

Adenocarcinoma of the pancreatic head is one of the most common gastrointestinal malignancies and, because of its aggressive nature, one of the hardest cancers to cure. The safety of surgical procedures for cancers of the pancreas has improved dramatically, but 5-year actual survival rates of patients who have undergone resection are still low (about 15%).¹ Cancer of the head of the pancreas is the prototypical tumor that causes painless jaundice; however, other cancers that obstruct the bile ducts also cause jaundice, including extrahepatic bile duct cancer, ampullary malignancy, duodenal cancer, and gallbladder cancer. Some of the following discussion is generalized to determining the diagnosis in patients presenting with obstructive jaundice [see 5:3 *Jaundice*].

Clinical evaluation *History* The classic presentation of cancer of the head of the pancreas is unremitting jaundice, usually accompanied by dark urine, light stool, and pruritus. Darkening of the urine or pruritus is often the first symptom, and scleral icterus frequently is first noted by family members

or coworkers. The pruritus is often severe. The jaundice sometimes is painless but more frequently is associated with epigastric pain, which is often mild. Severe acute pain is more often associated with other conditions that may cause jaundice (e.g., choledocholithiasis and pancreatitis). Back pain suggests that the tumor has invaded tissues outside the pancreas and is unresectable. Significant weight loss (> 10% of body weight) is common even when the pancreatic cancer is resectable.

In some patients, the presenting symptom is steatorrhea or diarrhea from obstruction of the pancreatic duct, weight loss, pain, or a combination of these rather than jaundice. Steatorrhea or diarrhea in the absence of jaundice is usually the result of a tumor in the uncinate process that obstructs the pancreatic duct but not the bile duct. Often these symptoms are overlooked until the tumor extends and causes jaundice. About 5% of patients have a history of diabetes of recent onset. Migratory thrombophlebitis (Trousseau sign) is uncommon and usually signifies metastatic disease. Pancreatobiliary malignancies cause biliary obstruction, but such obstruction is not commonly associated with biliary tract infection unless instruments have been employed in the biliary tree. Therefore, other diagnoses should be suspected in patients presenting with cholangitis who have not undergone biliary tract instrumentation. Patients with pancreatic cancer may also present with acute pancreatitis as the first manifestation. Vomiting and gastrointestinal (GI) bleeding are uncommon presenting symptoms and suggest the presence of advanced tumors that are obstructing or eroding the duodenum.

Physical examination Examination reveals scleral icterus. In some cases, the distended gallbladder may be palpable. In advanced cases, signs of metastatic disease (e.g., hepatomegaly and ascites) may be detected.

Investigative studies *Laboratory tests* Liver function tests (LFTs) are of limited value in diagnosis. The serum bilirubin level is elevated in jaundiced patients, with the direct fraction exceeding 50%. The serum alkaline phosphatase level is almost always elevated when the bile duct is obstructed, and levels three to five times normal are common. Aminotransferase levels usually are moderately elevated as well. Very high aminotransferase levels suggest a hepatocellular cause of jaundice, usually viral, although impaction of a stone in the bile duct can cause transient rises in serum aspartate aminotransferase to levels higher than 1,000 IU/mL. By themselves, LFTs cannot effectively distinguish among jaundice arising

from a hepatocellular cause (e.g., viral hepatitis or drug-induced cholestasis), jaundice resulting from a disease of microscopic bile ducts (e.g., primary biliary cirrhosis), or jaundice caused by any of the malignancies that obstruct the major bile ducts. To make this distinction, radiologic imaging tests are required [see *Imaging, below*].

Serum concentrations of the tumor marker CA 19-9 are often elevated in patients with pancreatic or biliary adenocarcinomas.² The upper limit of the normal range is 37 U/mL. Concentrations higher than 100 U/mL are highly suggestive of malignancy, but elevations between 37 and 100 U/mL are less specific. Serum levels generally reflect the extent of the tumor: small tumors (1 cm in diameter) are rarely associated with levels higher than 100 U/mL, whereas very high concentrations (> 1,000 U/mL) suggest metastatic disease. High levels may also accompany cholangitis, but these levels should subside to normal with relief of obstruction or infection, when malignancy is absent. Measurement of CA 19-9 concentrations may be employed to detect recurrences. In patients who have elevated CA 19-9 levels that return to normal after tumor resection; a second rise in the CA 19-9 level in the follow-up period is indicative of recurrence.

Imaging Several different diagnostic imaging tests may be used in jaundiced patients, including computed tomography (CT), magnetic resonance imaging (MRI), endoscopic retrograde cholangiopancreatography (ERCP), endoscopic ultrasonography (EUS), and transabdominal ultrasonography. The technical advances in imaging achieved over the past few years are remarkable. CT and MRI can now provide high-quality images of blood vessels and ducts and their anatomic relation to tumors. These images can even be projected in three dimensions if desired, although, to date, no high level studies have shown an advantage for this type of display.

Selection of appropriate imaging tests in a jaundiced patient is influenced by patient characteristics and by the symptoms observed. For instance, the type and order of investigations appropriate for an older patient presenting with obstructive jaundice, who is likely to have a malignancy, differ from those appropriate for a young woman with severe pain, who is more likely to have choledocholithiasis. The best initial imaging test in a patient in whom malignancy is suspected is either a fine-cut (3 mm between slices) three-phase (no-contrast phase, arterial phase, and venous phase) helical (spiral) CT scan or a high-quality MRI scan. Although MRI has the advantage of being able to provide a cholangiogram (i.e., magnetic resonance cholangiopancreatography [MRCP]), small and medium-sized radiologic facilities currently tend to be more skilled at CT than at MRI; this difference should be taken into account when the first test is ordered. High-quality MRI scanners and the very latest generation of CT scanners are capable of providing cholangiograms and angiograms, as well as axial images.

The typical pancreatic cancer appears as an area of reduced attenuation (darker zone) in the pancreatic head [see *Figure 1*], associated with upstream dilatation of bile ducts and the gallbladder. Often the pancreatic duct is also obstructed. As a result, the pancreatic duct may be dilated in the tail, body, and neck of the pancreas, with dilatation terminating sharply at the edge of the tumor. Pancreatic duct dilatation is often accompanied by atrophy of the body and the tail of the pancreas [see *Figure 2*].

When a jaundiced patient is discovered to have a typical-appearing localized cancer of the pancreatic head on CT scanning, no further diagnostic tests are needed, and operative management should be the next step. Tissue diagnosis is unnecessary. Negative biopsy results rarely change the therapeutic approach, and in that they may be falsely negative, they are

Figure 1 Shown is a typical hypoattenuating cancer of the pancreatic head. The tumor (arrow) is invading the right side of the portosplenic confluence, as evidenced by the “beaking” of the vein at that point.

Figure 2 In the same patient as in Figure 1, pancreatic duct dilation is apparent in the body of the pancreas, with atrophy of the parenchyma.

potentially misleading. Furthermore, omitting biopsy eliminates the small risk of tumor implantation in the needle tract. Selection of axial imaging as the first test often renders diagnostic ERCP, which is a more invasive test, unnecessary as well. Cholangiography also is not required for staging pancreatic head tumors [see Surgical Staging, below]. The advantages of starting with axial imaging in jaundiced patients with suspected cancer are discussed in greater detail elsewhere [see Biliary Tract Cancer, Extrahepatic Cholangiocarcinoma, Upper Duct Cholangiocarcinoma, Investigative Studies, below].

Additional diagnostic imaging for atypical CT or MRI findings In many patients with adenocarcinoma of the pancreatic head, the typical CT findings described above are absent and additional diagnostic imaging is required. Such patients may be categorized into two groups: those with an *atypical mass* and those with *no mass* on axial imaging. In either case, before ordering additional tests, it is appropriate to determine whether the CT scan is of adequate quality. The scan may have been performed without contrast, the arterial and venous phases may not have been captured appropriately, or the slice thickness may have been too great for precise visualization of the head of the pancreas. Small adenocarcinomas may be missed when the venous phase is poorly timed, especially if slice thickness is 5 mm or greater, and masses that initially appear atypical may exhibit a typical appearance when the CT scan is optimized. Neuroendocrine cancers commonly display arterial-phase enhancement, which will be missed if the scan is mistimed. In our experience, about 40% of referred patients who underwent CT scanning before arrival require a so-called pancreas protocol CT scan (i.e., a fine-cut three-phase helical scan) when they are first seen; in many of these cases, the second CT scan yields important diagnostic findings.

When no mass is present in a jaundiced patient with a periampullary tumor or another focal obstructing process (e.g., pancreatitis), the CT scan usually shows bile duct dilatation extending down to the intrapancreatic portion of the duct. The dilatation may terminate anywhere from the upper border of the pancreas to the duodenum, depending on the site of the tumor and the nature of the process obstructing the bile duct. In these conditions, ERCP is a good choice as the second test.

ERCP provides an endoscopic view of the duodenum that allows identification and biopsy of ampullary and duodenal tumors, which may be blocking the bile duct and producing jaundice. It confirms the presence of a bile duct stricture and displays its form, which is helpful in diagnosis. Focal strictures, especially those with shoulders, suggest malignancy. Long, tapering strictures limited to the intrapancreatic portion of the bile duct suggest chronic pancreatitis. Concomitant narrowing of the pancreatic duct in the head of the pancreas (the double-duct sign) suggests the presence of a small pancreatic cancer that is not visible on the CT scan. Longer or multiple pancreatic strictures suggest chronic pancreatitis. A single focal bile duct stricture in the absence of pancreatic duct abnormalities is the hallmark of cancer of the lower bile duct. Infiltrating cancers of the bile duct may cause more than one stricture along the bile duct, but when more than one stricture is present, other diagnoses (e.g., primary sclerosing cholangitis) should be considered. Both pancreatic and bile ducts may be assessed with brush cytology. This test

has a 45 to 50% sensitivity for cancer³; therefore, only a positive test result is significant.

ERCP findings in a patient with no mass must be evaluated in the light of findings from other investigations. Patients with the classic double-duct sign or single focal shouldered bile duct strictures are likely to have small pancreatic or bile duct tumors. Further diagnostic support is usually not needed before laparotomy, although such support may be reassuring when the CA 19-9 concentration is lower than 100 U/mL. When doubt persists, EUS often helps resolve it. EUS may identify a small mass that was not seen on the CT scan, and biopsies may then be done. Occasionally, EUS reveals enlarged lymph nodes, which may also undergo biopsy. However, negative EUS-guided biopsy results in patients who present with painless jaundice do not exclude malignancy. When such patients have an identifiable mass on EUS and a presentation in keeping with the diagnosis of cancer, pancreaticoduodenectomy is recommended, even if EUS-guided biopsy yields negative results. If a nonoperative approach is taken, short-term follow-up at 4 to 6 weeks with repeat imaging and biopsy is mandatory. If the findings persist, laparotomy is advisable.

Occasionally, preoperative testing reveals no mass, but a mass is subsequently discovered by intraoperative palpation or intraoperative ultrasonography (IOUS). A mass palpated in the head of a pancreas that is otherwise normal or near normal in texture in the remainder of the gland is highly suggestive of malignancy and constitutes sufficient justification for resection. The same is true of a mass detected by IOUS if the mass has characteristics of malignancy (i.e., is hypoechoic). If the IOUS findings are inconclusive, biopsy with frozen-section examination is a reasonable approach. In many such cases, the whole pancreas is diffusely firm or hard, and IOUS demonstrates a diffuse change in the normal texture of the gland. When the pancreas is diffusely firm and no localized process is seen on IOUS, biopsies should be directed toward the stent in the bile duct at the point where the bile duct narrows (as seen on ultrasonography).

The ultimate diagnostic test is pancreaticoduodenectomy. If there is a strong suspicion of cancer before laparotomy or the findings at laparotomy are strongly suggestive, this procedure should be performed without preliminary biopsy. When this approach is followed, a small number of patients with suspected malignant disease will be found to have benign disease; this possibility should be explained to patients who do not undergo confirmatory tissue diagnosis before operation. Because of the limited negative predictive value of currently available tests, pancreaticoduodenectomy is sometimes still required to make a definitive diagnosis.

The finding of an atypical pancreatic head mass on a CT scan poses an additional challenge. Atypical masses may take different forms. In some cases, they exhibit attenuation that differs only slightly from that of the surrounding pancreas; in others, they have a ground-glass appearance. They may extend into the body and tail of the pancreas, or they may be localized to the head. With atypical masses, the most common problem is how to differentiate focal pancreatitis from adenocarcinoma. This differentiation can be very difficult. Pancreatitis may be present without antecedent acute attacks; without a history of alcoholism, gallstones, or hyperlipidemia; without diabetes or steatorrhea; and without calcifications in the

gland. Cancer appears to be more common in patients who have had chronic pancreatitis, and the diseases may coexist. Therefore, one cannot feel confident that cancer is absent simply because chronic pancreatitis is present. Cancer should be suspected in patients with an established diagnosis of chronic pancreatitis who undergo a rapid change in status (e.g., weight loss). Diabetes is common in patients with chronic pancreatitis, but it may also be the first sign of pancreatic cancer in patients without chronic pancreatitis. Chronic pancreatitis can cause painless jaundice. A rare immune form of chronic pancreatitis, known as lymphoplasmacytic sclerosing pancreatitis, has been recognized that is particularly hard to differentiate from cancer.⁴ However, in these patients, the serum IgG4 level is characteristically elevated.

EUS is becoming increasingly important in the management of patients with atypical pancreatic head masses.⁵ When jaundice is present, EUS with or without ERCP is our usual approach; when it is absent, EUS alone is performed. EUS-guided biopsy is superior to CT-guided transabdominal biopsy in that access to the head of the pancreas is easier and the chance of needle tracking is reduced (because the biopsy is taken through the duodenal wall, which is resected if a Whipple procedure is done).

At the conclusion of all of the preceding investigations, it still may not be clear whether a malignancy is present. Clinical judgment must be exercised in deciding whether to operate or to repeat investigative studies after an interval of 2 to 3 months. Operation is favored in patients who are jaundiced, who have less pain, who have elevated CA 19-9 levels, and whose mass is suspicious for cancer. Elevation of the CA 19-9 concentration beyond 100 U/mL should be regarded as a very important finding. When EUS is inconclusive, ultrasound-guided diagnostic laparoscopy may be performed to obtain core tissue biopsies from several areas of the mass. This technique is especially useful when chronic pancreatitis is strongly suspected⁶ in that the multiple long core biopsies obtainable with this procedure provide a greater degree of assurance against false negative findings for cancer. Even this test, however, is not 100% accurate. The penultimate diagnostic test is laparotomy with mobilization of the pancreatic head and IIOUS-guided transduodenal core biopsies of the mass. The ideal outcome with this approach is to perform pancreaticoduodenectomy in all patients who actually have cancer while reducing to a reasonable minimum resection in patients with benign disease, who in most cases are better served by biliary bypass. Fortunately, today, because of improved axial imaging and EUS, a definitive preoperative diagnosis is usually available.

Surgical staging The term “staging” is currently used to denote the process by which the surgeon determines whether a tumor is resectable. We prefer to use the term “surgical staging” for this process so as to distinguish it from those staging classifications that define the life history and prognosis of tumors and provide the basis for comparison of results—namely, the TNM classifications developed by the American Joint Committee on Cancer (AJCC). These latter systems are also of great importance to the surgeon dealing with pancreatic tumors.

Surgical staging is started preoperatively and completed intraoperatively. Preoperative staging tests determine operability—that is, whether the tumor appears resectable after preoperative testing. However, the final decision regarding

resectability is made only during the operation, on the basis of intraoperative staging. A tumor of the head of the pancreas is deemed unresectable when it is determined to have extended beyond the boundaries of a pancreaticoduodenectomy. Common reasons for unresectability include (1) vascular invasion (i.e., invasion of the superior mesenteric vein, the portal vein, the superior mesenteric artery, or, less commonly, the hepatic artery); (2) lymph node metastases that fall outside the scope of a pancreaticoduodenectomy (e.g., metastases to para-aortic and celiac lymph nodes); (3) hepatic metastases; (4) peritoneal metastases; and (5) extra-abdominal metastases (usually pulmonary). Limited vascular invasion of the superior mesenteric vein and the portal vein may be overcome by resection and reconstruction and thus is only a relative contraindication to resection. This is especially true when the tumor is small and has arisen in the vicinity of the veins. In a series from our institution (Washington University in St. Louis), about 27% of resections done for pancreatic cancer involved resection of these veins.⁷ Recently, the term “borderline” has been introduced to describe tumors that are unresectable by standard criteria but that can be encompassed by extending the zone of resection.⁸ Usually, such tumors are first treated with chemoradiation. Attempts are also being made to downsize more advanced pancreatic tumors to a resectable state by chemotherapy and radiation. To date, no long-term studies have evaluated either approach. However, given the aggressive nature of this tumor, it is likely that chemotherapy and radiation will effectively downsize tumors in only a small number of patients, at least until much more effective chemotherapeutic agents are available.

The tests used to establish the diagnosis and those used to accomplish surgical staging go hand in hand. Abdominal CT scans, abdominal MRI, thoracic CT scans, and chest radiographs are obtained to detect hepatic metastases, vascular invasion, and pulmonary metastases. To assess vascular invasion, fine-cut three-phase helical CT scans or MRI scans are required. These tests may also detect enlarged lymph nodes, but it should be remembered that nodes may be enlarged for reasons other than cancer. Sometimes intraperitoneal fluid collections or peritoneal or omental nodules are identified; fluid may be sent for cytologic analysis, and omental nodules may undergo ultrasound-guided biopsy. Invasion of the mesentery, the mesocolon, or retroperitoneal tissues may also be detected by CT scanning. In the view of some surgeons, such invasion may render the tumor unresectable, but in our experience, this is rarely the case in the absence of concomitant vascular invasion: the resection may still be accomplished with clear margins by resecting the portion of the mesocolon or the mesentery that is locally invaded.

EUS may be used to guide biopsy of suspicious lymph nodes when these lie outside the planned resection zone. It has also been employed to assess vascular invasion, but in our experience, it has no advantage over CT in this regard; moreover, it is more operator dependent than CT. Staging laparoscopy is particularly effective at finding small hepatic and peritoneal nodules. About 20% of patients thought to have resectable pancreatic adenocarcinoma of the head of the pancreas before staging laparoscopy are found to have liver or peritoneal metastases at laparoscopy.⁹ Staging is completed intraoperatively by carefully inspecting the intra-abdominal

contents, including the lesser sac, mobilizing the head of the pancreas, performing biopsies of suspicious nodules or nodes outside the planned resection zone, and attempting dissection of the superior mesenteric vein or the portal vein. Formal clinicopathologic staging according to the AJCC's TNM system is useful for establishing the prognosis and planning additional treatment [see Table 1 and Table 2].

All authorities agree that axial imaging of the abdomen and chest (or roentgenography of the chest) is standard practice for staging pancreatic cancer; however, not all agree on the value of other staging tests. Many authorities advocate omission of staging laparoscopy or EUS-guided biopsy of nodes on the grounds that patients are better served by palliative surgery than by endoscopic stenting of the bile duct. There is no advantage in knowing preoperatively whether small liver metastases or celiac node metastases are present if laparotomy is to be undertaken anyway. Trials examining whether better palliation is offered by surgical bypass or endoscopic stenting report conflicting results; on balance, surgical bypass is still a very good treatment for localized unresectable tumors in younger patients without serious comorbidities. We no longer perform staging laparoscopy in patients with adenocarcinoma of the pancreas except in patients who are suspected to have liver or peritoneal metastases on axial imaging. Finally, ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET) may be useful in staging pancreatic cancer. Given that inflammation is frequently confused with cancer, the major role of this modality will probably be in the detection of distant metastases.

Management *Preoperative preparation* All jaundiced patients should receive vitamin K, a fat-soluble vitamin whose absorption is reduced by biliary or pancreatic duct obstruction. Routine preoperative bile duct decompression is unnecessary, except when jaundice has been prolonged or operative

treatment will be delayed (e.g., for correction of cardiac or other comorbid conditions). Several studies have shown that surgical outcome is not improved by routine preoperative decompression in jaundiced patients. In fact, stent placement may increase the incidence of postoperative infection.¹⁰

Rationale for pancreaticoduodenectomy The technical details of pancreaticoduodenectomy are discussed more fully elsewhere [see 5:24 *Procedures for Benign and Malignant Pancreatic Disease*]. Therapeutic decision making necessarily includes consideration of the extent of the procedure. The operative goal is to remove the tumor with clear margins, as well as the N1 regional lymph nodes. Attempts have been made to improve results by extending the operation, either through more extensive lymph node dissections¹¹ or through resections of superior mesenteric, hepatic, or celiac arteries.¹² Four randomized trials have now shown no advantage for extended lymph node dissection. Resection of celiac or superior mesenteric arteries has also not been successful in improving overall survival. The lesson seems to be that invasion of additional lymph node regions (N2) or the superior mesenteric or celiac arteries signals an aggressive tumor biology that is unlikely to be overcome by wider resections. Except for resection of the portal vein or the superior mesenteric vein and perhaps short segments of the hepatic artery to address invasion of these structures by otherwise favorable tumors, extended resections are generally unsuccessful. Even these recommended vascular resections are probably best restricted to tumors that have arisen close to the particular vessels and involved them while still small; resections of large adenocarcinomas that have grown over time to involve long stretches of the veins are best avoided. These comments do not apply to tumors that initially might have required resection of the celiac or superior mesenteric arteries but that have been downsized by chemotherapy or chemoradiation so that they can be resected without such vascular resections.

There is also continuing controversy regarding the respective merits of the standard version of the operation and its pylorus-preserving variant. There is no evidence that the two procedures differ with respect to overall survival. Pylorus preservation is associated with gastric-emptying problems in the postoperative period, but, overall, it may be associated with slightly less postoperative GI dysfunction.¹³ We employ pylorus preservation selectively in older, thinner patients, with the aim of minimizing disruption of GI function.

Adjuvant therapy is often given in resected patients; however, there is controversy regarding the role of chemotherapy

Table 1 American Joint Committee on Cancer TNM Clinical Classification of Pancreatic Cancer¹

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor limited to pancreas, ≤ 2 cm in greatest dimension
	T2	Tumor limited to pancreas, > 2 cm in greatest dimension
	T3	Tumor extends beyond pancreas but without involvement of celiac axis or SMA
	T4	Tumor involves celiac axis or SMA
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	No distant metastasis

SMA = superior mesenteric artery.

Table 2 American Joint Committee on Cancer Staging System for Pancreatic Cancer

Stage	T	N	M
0	Tis	N0	M0
IA	T1	N0	M0
IB	T2	N0	M0
IIA	T3	N0	M0
IIB	T1, T2, T3	N1	M0
III	T4	Any N	M0
IV	Any T	Any N	M1

versus chemoradiation. Randomized trials have shown that chemotherapy is beneficial and have questioned the role of radiotherapy. The latter may be helpful when an R1 resection has been performed.

Adenocarcinoma of Body and Tail of the Pancreas

Adenocarcinoma of the body and tail of the pancreas is less common than adenocarcinoma of the head. Because it does not produce jaundice, it tends to be recognized relatively late. Accordingly, patients are often in an advanced stage of disease at presentation. Tumors of the midbody tend to invade posteriorly to involve the superior mesenteric artery or the celiac axis, even when these lesions are only 2 to 3 cm in diameter. As a result, tumors of the tail are more likely to be resectable than tumors of the midbody when they are discovered. Many resectable tumors are discovered incidentally; by the time the tumors give rise to symptoms, they are frequently unresectable.

Clinical evaluation Symptoms are nonspecific, consisting of abdominal and back pain (which is usually relieved by sitting up and leaning forward), weight loss, and diabetes of recent onset.

Investigative studies The CA 19-9 concentration may be elevated. CT usually shows a lucent (hypoattenuating) mass [see Figure 3], often with extension outside the pancreas and dilatation of the distal pancreatic duct, when the tumor is proximal to the tail of the gland. EUS is very useful for assessing indeterminate lesions.

Surgical staging Surgical staging of cancers of the body and the tail is similar to that of cancers of the pancreatic head and is based primarily on CT scanning of the abdomen and the thorax. Unresectability by reason of local invasion is usually attributable to the involvement of the superior mesenteric artery, hepatic artery, or the celiac artery and less commonly to the involvement of the portal vein, the superior mesenteric

vein, or the aorta. Another indicator of unresectability is enlarged para-aortic nodes. Invasion of the spleen, the stomach, the left adrenal gland, the mesocolon, the colon, the retroperitoneum, or even the left kidney is not a contraindication to resection provided that clear margins may be expected.¹⁴ Staging laparoscopy is of great value: between 20 and 50% of patients with these tumors are found to have unresectable tumors with this modality, usually due to small liver or peritoneal implants.¹⁵ Cancer of the body and the tail differs from cancer of the head in that there is no effective palliation and therefore no rationale for laparotomy if the lesion is unresectable. Celiac nerve block, which is very helpful in reducing the use of narcotics for pain control, may also be performed laparoscopically or endoscopically.

Management *Rationale for radical antegrade modular pancreatosplenectomy* Logically, the goal of resection of tumors of the body and tail should be the same as that of resection of tumors of the head—namely, excision of the tumor with clear margins, along with the N1 lymph nodes. In practice, this goal generally is not achieved by the traditional retrograde distal pancreatectomy, in which the spleen is taken first and which is not based on the lymph node drainage of the pancreas. Lymph node counts have been low with the traditional procedure, and positive posterior margin rates have been high. As an alternative, we have developed a technique referred to as radical antegrade modular pancreatosplenectomy (RAMPS), which accomplishes the desired goals by performing the resection in an antegrade manner from right to left and which is based on the established lymph node drainage of the gland [see Figure 4].¹⁶ Negative tangential margin rates of 90% have been achieved with this approach. RAMPS also allows early control of the vasculature.

Mucinous Adenocarcinoma

Mucin-producing cancers are special variants of adenocarcinoma of the pancreas that often arise in preexisting lesions. The two main types of premalignant lesions are mucinous cystic neoplasm (MCN) and intraductal papillary mucinous neoplasm (IPMN) (also referred to as intraductal papillary mucinous tumor).¹⁷ A complete discussion of pancreatic cyst disease is beyond the scope of this chapter. Accordingly, we briefly address such disease as it relates to cancer of the pancreas, omitting discussion of less common cystic malignancies of the pancreas.

Mucinous cystic neoplasm MCN occurs most often in middle-aged women, typically in the body or tail of the pancreas. MCNs are unilocular or septated cysts whose diameter ranges from subcentimeter size to 15 cm or larger. Occasionally, calcium is present in the wall. Excrescences may be present on the inner wall; if so, malignancy is more likely. Most symptomatic MCNs are between 4 and 7 cm in diameter.

Clinical evaluation and investigative studies Patients with MCNs typically present with left-sided abdominal pain, often in the flank and the back. These lesions also are frequently discovered incidentally. Pancreatitis is rare and jaundice is uncommon, even when the lesions are situated in the head of the pancreas. MCNs must be differentiated from pseudocysts and from serous cystadenomas (SCAs), which are benign cysts. Differentiation between MCNs and pseudocysts is based on the history, imaging studies, and cyst fluid analysis. The diagnosis of pseudocyst is supported by a history of pancreatitis,

Figure 3 Shown is a typical hypoattenuating cancer of the tail of the pancreas with invasion of the hilum of the spleen and the splenic flexure of the colon. Peritumoral stranding suggests inflammation or invasion of peripancreatic fat.

Figure 4 Illustrated is the pattern of lymphatic drainage of the pancreas. The darker nodes are N1 nodes for the body and tail of the pancreas. The lighter nodes on the aorta to the left side of the celiac artery and the superior mesenteric artery are N1 for the central part of the pancreas and N2 for other regions.

a thick-walled, uncalcified cyst with associated radiologic signs of pancreatitis and often cholelithiasis, as well as cyst fluid containing high levels of amylase and lipase and a relatively low level of carcinoembryonic antigen (CEA) (< 500 ng/mL).

SCAs have the same clinical presentation as MCNs. SCAs are more frequently polycystic than MCNs, but this difference is not a certain means of discriminating between the two. In a minority (25%) of cases, SCAs have a pathognomonic central calcification with radiating arms ringed by multiple grape-sized cysts. When the individual cysts are tiny (honeycomb pattern), there are many cyst walls within the lesion, and then SCAs may be mistaken for solid tumors. Unlike pseudocysts and IPMNs, neither MCNs nor SCAs communicate with the pancreatic duct, although they may compress it. Measurement of the CEA level in cyst fluid is a good means of distinguishing MCN from SCA. SCAs have very low levels of CEA, with the cutoff being 5 ng/mL.¹⁸ The cyst fluid obtained from MCNs is often mucinous, and cytologic assessment may show mucin-producing cells; typically, the fluid is high in CEA. The CA 19-9 concentration may also be used to distinguish MCNs from SCAs, but it is not as reliable as the CEA concentration for this purpose.¹⁸

Surgical staging Surgical staging is required when investigations suggest that MCNs are malignant. Essentially, the same methods are used as for any pancreatic adenocarcinoma (see above). Malignancy is suggested by a solid intracystic or extramural component. Sometimes a mucinous tumor is frankly malignant with a large or dominant solid component. Such a tumor is better termed a mucinous cystadenocarcinoma, and it should be evaluated and treated from the outset in the same manner as other adenocarcinomas of the pancreas.

Management In symptomatic patients, preoperative differentiation between MCNs and SCAs is unnecessary because

resection is the treatment for both. In asymptomatic patients, MCNs more than 4 cm in diameter should be excised because of the possibility of malignant degeneration.¹⁹ MCNs associated with internal excrescences or associated with a local solid mass should be removed independent of the size of the cyst.¹⁹ The standard procedure has been open distal pancreatectomy with splenectomy, although lesser procedures, such as spleen-sparing distal pancreatectomy, central pancreatectomy, and enucleation, have all been used as well. Recently, laparoscopic distal pancreatectomy with or without sparing of the spleen has emerged as the procedure of choice because of the advantages of reduced postoperative pain and shortened length of stay.²⁰ These procedures appear to be reasonable choices provided that there is no suggestion of invasive malignancy on imaging (i.e., that there are no excrescences on the inner lining and that the surrounding pancreas appears normal). In these cases, a more formal resection that obeys oncologic goals such as a RAMPS procedure should be employed. Enucleation may be associated with a higher incidence of postoperative fistula. If invasive cancer is not detected in the resected specimen, the chances that the malignancy will recur are small; in fact, we have never seen such a recurrence.

The 4 cm cutoff for surgical treatment of MCNs in asymptomatic patients¹⁹ without other signs associated with malignant degeneration is reasonable, but recommendations could change based on additional studies of natural history. Furthermore, it is still possible that malignant degeneration could occur in smaller cysts, although the probability is low. Many cysts smaller than 2 cm are found in the course of axial imaging performed for other reasons. Such cysts are difficult to diagnose because of the small volume of cyst fluid present, and the benefit to be gained from performing a large number of pancreatectomies for these small cysts is questionable, even

when they are diagnosable as MCNs. Occasionally, MCNs or symptomatic SCAs are located in the head of the pancreas and require pancreaticoduodenectomy. Some authorities feel that very large asymptomatic SCAs should also be excised because of rare instances of malignant degeneration.

Intraductal papillary mucinous neoplasm IPMN begins as a metaplastic change in the cells lining the pancreatic ducts altering from a low cuboidal serous type of cell to a mucin-producing type. These cells are prone to progress to dysplasia and eventual malignant transformation. Overall, IPMNs appear to undergo malignant transformation more frequently than MCNs. There are two recognized types of IPMN, which may occur either separately or together.^{19,21} The more common type affects the main pancreatic duct [see Figure 5] and is called “main duct IPMN.” In this type, the main pancreatic duct becomes dilated and filled with mucin. As the disease progresses toward malignancy, papillary processes may project into the lumen. The less common type, called “side-branch IPMN,” affects the smaller ducts and presents as multiple (usually small) pancreatic cysts. In either type of IPMN, the disease may be either diffuse or focal; when it is focal, the head of the pancreas is the site of disease in the majority (60%) of cases. About 20% of IPMN patients have a malignancy at the time of diagnosis, although the cancer may not be evident until the specimen is examined pathologically.

Clinical evaluation and investigative studies^{19,21} IPMN occurs predominantly in males and usually affects patients in their sixties. Pain (usually attributable to pancreatitis arising as a result of mucous obstruction of the pancreatic duct) is a common presenting symptom. Another common presentation is pancreatic insufficiency with diabetes or steatorrhea. Accordingly, it is not surprising that, formerly, many IPMN patients were diagnosed as having chronic pancreatitis. IPMN may also be discovered incidentally or may present as a cancer with signs and symptoms similar to those of other pancreatic cancers, depending on the part of the gland in which they arise. On rare occasions, cholangitis from obstruction of the common channel by mucus is the presenting problem.

The diagnosis is made on the basis of the presentation and the findings from axial imaging and ERCP. The characteristic ERCP findings are a dilated papillary orifice (“fish mouth”) with mucus bulging from the orifice and a dilated pancreatic duct when contrast is injected. Sometimes, mucus prevents complete filling of the duct with dye. In this situation, CT scans or MRI with MRCP may be quite useful for detecting ductal dilatation and atrophy of the pancreas. MRCP is best at detecting excrescences projecting from the wall of the duct into the lumen. These signal progression of the disease toward neoplasia. In side-branch IPMN, ERCP (and often MRCP) typically demonstrates communication between the cysts and the main duct, which is often normal in size; this finding is not present in MCN or SCA and is very useful for distinguishing side-branch IPMN from these other types of cysts.

Management Knowledge of this entity is evolving, and recommendations are the current ones.^{19,21–23}

Large duct IPMN As this entity is highly premalignant, resection is indicated once the diagnosis is made. Pancreatoduodenectomy is usually required as the disease affects the duct in the head of the pancreas in most cases. Although the duct in the body and tail of the gland may be dilated, this does not mean that it is involved in dysplastic changes as dilation may be secondary to obstruction caused by the viscous mucus in the proximal duct.²¹ Therefore, the decision of whether to perform a complete pancreatectomy is made at the time of pancreatoduodenectomy, based on frozen section of the transected pancreatic neck. In most cases, the frozen section will show normal ductal epithelium or only mild or moderate dysplasia. Such patients do not require more pancreas to be resected. Occasionally, carcinoma, carcinoma in situ, or severe dysplasia is found, necessitating the resection of part or all of the remaining pancreas.²¹

Small duct IPMN This entity is less likely to degenerate into malignancy, and the probability of malignant degeneration is related to size.²² Current indications for resection are cysts exceeding 3 cm in diameter or smaller cysts that are

Figure 5 (a) Computed tomographic scan of a patient with main duct intraductal papillary mucinous neoplasm involving the entire length of the pancreatic duct (arrows) reveals substantial distention of the duct. (b) Shown is a cross section through the resected specimen.

associated with symptoms, internal excrescences, pericyst solid tumor, or pancreatic duct obstruction manifested as a dilation of the duct distal to the cyst.

With either type of IPMN, lifelong follow-up with axial imaging is needed.²¹ This problem should be thought of as a field defect in the pancreas. Large duct and small duct IPMNs may coexist, and pancreatic intraepithelial neoplasia (PanIN) lesions (dysplastic lesions of the duct) may coexist with IPMN.

Most patients who require total pancreatectomy tolerate the procedure well when they are enrolled in a program keyed to this operation. Frank mucinous cancers may appear in patients with IPMN as well; they should be managed in much the same fashion as other adenocarcinomas, with the additional requirement that the resection should encompass the entire IPMN-bearing portion of the pancreas. The mucinous cancers associated with IPMN have a better prognosis than ductal adenocarcinomas do.^{21,23}

NEUROENDOCRINE CANCERS

Neuroendocrine cancers account for fewer than 5% of surgically treated pancreatic malignancies. Some of these cancers are functional tumors, which produce hormones that lead to paraneoplastic syndromes. Examples include insulinoma, gastrinoma, glucagonoma, and vasoactive intestinal polypeptide-secreting tumor (VIPoma), all of which are associated with characteristic clinical syndromes. These syndromes are often produced while the tumors are still small. A detailed discussion of functional neuroendocrine tumors is beyond the scope of this chapter.

Other neuroendocrine tumors are nonfunctional and, as a result, reach a larger size before giving rise to symptoms. These lesions present with symptoms caused by mass effect and must be differentiated from ductal adenocarcinomas. Nonfunctional neuroendocrine cancers are relatively slow-growing tumors that tend to push rather than invade structures but are capable of metastasizing to lymph nodes, as well as to the liver and other organs. Pain is the most common presenting symptom. Jaundice, pancreatitis, and systemic symptoms (e.g., weight loss) are less common with these tumors than with adenocarcinoma of the pancreas. Because of the propensity of neuroendocrine tumors to deflect rather than invade the bile duct, jaundice may be absent even when tumors are located in the head of the gland.

Diagnosis, surgical staging, and treatment rationale are essentially the same for neuroendocrine cancers as for ductal adenocarcinomas. On CT scans, these lesions characteristically show enhancement in the arterial phase and are seen to push on bile ducts and vascular structures rather than encase them. Complete resection by means of pancreatoduodenectomy or distal pancreatectomy [see 5:24 *Procedures for Benign and Malignant Pancreatic Disease*] is indicated. Given the slow growth rate of neuroendocrine cancers and their relatively favorable prognosis (a 50 to 60% 5-year survival rate), removal of the primary lesion and any hepatic secondary lesions is justified if all tumor tissue can be removed with clear margins.

Biliary Tract Cancer

Cancers of the biliary tract (cholangiocarcinomas) may arise at any level of the biliary tree from the smallest, most

peripheral intrahepatic bile duct to the termination of the common bile duct. The lesions may be subdivided into intrahepatic and extrahepatic cholangiocarcinomas. The former are described below under “Liver Tumors.” Cholangiocarcinomas may grow in one of three phenotypic forms, a mass, a stricture, or an intraluminal polyp or excrescence, although combinations of these forms in different parts of the tumor may be present. The formal designations are “mass forming” (MF), periductal infiltrating (PI), and intraductal growth (IG). The type of growth pattern may affect the clinical presentation.

EXTRAHEPATIC CHOLANGIOCARCINOMA

Extrahepatic cholangiocarcinoma (CCA) may be subdivided into lower duct CCA and upper duct CCA, with the former arising in the intrapancreatic or retroduodenal portion of the bile duct and the latter arising above it. In practice, most upper duct CCAs (also referred to as hilar CCAs or Klatskin tumors) arise just below the union of the right and left hepatic ducts, at the union of the ducts, or in the main right or left hepatic ducts. Cancer of the midportion of the bile duct at the usual insertion point of the cystic duct is more likely to be an extension of a gallbladder cancer than a primary CCA. AJCC staging criteria for these tumors are useful for establishing the prognosis and planning further treatment [see Table 3 and Table 4].

Table 3 American Joint Committee on Cancer TNM Clinical Classification of Extrahepatic Bile Duct Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor confined to bile duct histologically
	T2	Tumor invades beyond wall of bile duct
	T3	Tumor invades liver, gallbladder, pancreas, or unilateral branches of portal vein or hepatic artery
	T4	Tumor invades any of the following: main portal vein or branches bilaterally, common hepatic artery, or other adjacent structures (e.g., colon, stomach, duodenum, or abdominal wall)
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastases cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

Lower Duct Cholangiocarcinoma

Clinical evaluation and investigative studies Much of what the surgeon needs to know about lower duct CCA has already been addressed elsewhere [see Pancreatic Cancer, Adenocarcinoma of the Head of the Pancreas, *above*]. By far the most common presentation is painless jaundice with its constellation of associated symptoms (especially pruritus). Laboratory tests reveal the characteristic pattern of obstructive jaundice. A serum CA 19-9 concentration higher than 100 U/mL facilitates the diagnosis. Axial imaging reveals dilation of the intrahepatic bile ducts, the gallbladder (in most cases), and the extrahepatic bile ducts down to the level of the pancreatic head, where the dilatation terminates abruptly. Usually, no mass is visible. ERCP or MRCP shows a focal stricture, and ERCP brushings are positive in about 50% of cases. EUS may be helpful in that it is more sensitive for small tumors than CT. Needle biopsy is directed toward the mass or, if no mass is visible, toward the narrowest segment of the bile duct. A negative biopsy result does not rule out a small bile duct cancer. “Spyglass” cholangioscopy, in which a small endoscope is directed into the biliary tree along a catheter placed by duodenoscopy, facilitates direct biopsy of the bile duct wall and lesions that project into the lumen.

The differential diagnosis includes other potential causes of focal strictures of the bile duct.²⁴ The most common cause of a benign stricture of the intrapancreatic bile duct is pancreatitis, which may be diffuse or focal. Other causes of benign stricture include iatrogenic injury, choledocholithiasis, sclerosing cholangitis, and benign inflammatory pseudotumors [see Upper Duct Cholangiocarcinoma, Investigative Studies, Imaging, *below*]. Iatrogenic injuries rarely involve the intrapancreatic portion of the bile duct, although such injuries can occur in this area as a consequence of forceful instrumentation. Sclerosing cholangitis may affect this section of the bile duct but usually affects other areas of the biliary tree as well. The diagnostic steps for differentiating benign neoplasms from malignant tumors are essentially the same for lower duct CCA as for pancreatic cancer. As noted, resection may be required to make the diagnosis. In any patient presenting with jaundice and a focal stricture of the bile duct, lower duct CCA should be strongly suspected. Mass-forming bile duct cancers may also arise in the lower bile duct, but, for obvious reasons, they are difficult to differentiate from pancreatic adenocarcinomas. Perhaps in the future genetic profiling will permit this to be done. The surgical workup and management are identical.

Surgical staging Surgical staging of lower duct CCAs is usually straightforward. These tumors are usually remote from major vascular structures and thus are not subject to the same local staging considerations as adenocarcinomas of the pancreatic head are. The exception is a tumor that extends to the top of the retroduodenal portion of the bile duct. At this point, the bile duct is apposed to the portal vein and the hepatic artery, and these structures may be invaded by bile duct tumors in this location.

Management The treatment for resectable lesions is pancreaticoduodenectomy, and the rationale for the extent of the resection is the same as for adenocarcinoma of the head of the pancreas.

Upper Duct Cholangiocarcinoma

Upper duct (or hilar) CCA is a sporadically occurring tumor that may also be seen in patients with primary sclerosing cholangitis, ulcerative colitis, or parasitic infestation. It is characteristically slow growing and locally invasive, and it metastasizes more readily to lymph nodes than systemically, although intrahepatic and peritoneal metastases are not uncommon. Most hilar CCAs are cicatrizing diffusely infiltrating cancers (PI tumors), but some form masses (MF type), and others present as papillary ingrowths (IG type). These tumors are also subdivided by the upper level of the tumor in the biliary tree according to the Bismuth classification [see Figure 6].²⁵

When the CCA originates in one of the hepatic ducts, that duct may be obstructed for a considerable period before the tumor causes jaundice by growing into the other hepatic duct or the common bile duct. Such prolonged unilateral obstruction before the onset of the presenting symptom of jaundice may result in atrophy of the obstructed side of the liver, which may affect subsequent management. For example, because the disease is more advanced on the obstructed side, the atrophied half of the liver will be removed in almost all cases in which resection is indicated. In addition, when one side of the liver undergoes atrophy, the other side undergoes hypertrophy. These changes may lead to rotation of the liver, which, in turn, may cause the structures in the hepatoduodenal ligament to be rotated out of their normal anatomic location. For instance, if hypertrophy of the left hemiliver develops, the hepatic artery may come to lie directly in front of the bile duct.

Clinical evaluation The usual presentation of hilar CCA consists of painless jaundice with its accompanying symptoms (especially pruritus), although some pain may be present. Cholangitis before instrumentation of the bile duct is uncommon. In patients who present in the late stages of the disease, general manifestations of cancer (e.g., malaise, weight loss, or ascites) may be noted. In patients with primary sclerosing cholangitis, the presence of CCA is often suggested by a rapid deterioration in the patient’s general condition. It is not unusual for patients with hilar CCA to have undergone a cholecystectomy in the recent past; the symptoms of pain and jaundice may be mistaken for symptoms of gallbladder disease in patients who happen also to have gallstones.

Investigative studies *Laboratory tests* Laboratory testing follows the pattern previously described for obstructive jaundice [see Pancreatic Cancer, *above*]. Again, the most helpful diagnostic laboratory test is the serum CA 19-9 concentration: levels higher than 100 U/mL are strongly suggestive of cancer.

Figure 6 Depicted is the Bismuth classification of hilar cholangiocarcinoma (a through e).

Imaging Earlier [see Pancreatic Cancer, Ductal Adenocarcinoma, Adenocarcinoma of the Head of the Pancreas, *above*], the point was made that it is preferable to employ axial imaging rather than ERCP as the first imaging test in the jaundiced patient because doing so will often render ERCP, an invasive test, unnecessary. This point carries even more force in the setting of hilar CCA. Injection of dye above the malignant stricture is an integral part of ERCP. Once the dye has been injected, stents must be placed to prevent post-ERCP cholangitis. This process may involve insertion of bilateral stents, including a stent in the atrophic hemiliver. Bilateral stenting is disadvantageous because the aim is to encourage atrophy of the hemiliver to be resected and hypertrophy of the hemiliver to be retained, and insertion of a stent in the atrophic side negates that aim. Starting with CT or MRI rather than with ERCP allows detection of any hilar CCA present simultaneously with detection of atrophy. At this point, the patient can be evaluated by a multidisciplinary team with expertise in this disease, and a decision can be made regarding which side of the biliary tree to decompress (if either). Whether stents should be employed in treating hilar CCA is debatable, but if a stent is inserted, only the side

to be retained should be intubated. MRCP now provides resolution that is close to that obtained with direct cholangiography [see *Figure 7*].

ERCP does have one significant advantage in that it allows brushings to be obtained. Standard brushing techniques at this high level in the biliary tree are even less sensitive than those at lower levels, but spyglass technology (see *above*) has opened this area of the biliary tree to direct biopsy on a routine basis. EUS has been employed to obtain diagnostic tissue, with some degree of success; however, because the biopsy needle passes through the peritoneal cavity, concerns have been expressed regarding possible tumor seeding. Such seeding has not been an issue with lower duct cancers, because the biopsy tract is entirely within the future resection specimen. In many cases, a tissue diagnosis cannot be obtained preoperatively, and the diagnosis is based on the presence of a focal hilar stricture that causes jaundice.

Focal strictures of the upper bile ducts are strongly suggestive of cancer, but CCAs must also be differentiated from benign inflammatory tumors (also referred to as hepatic inflammatory pseudotumors and benign fibrosing disease).²⁶ These inflammatory masses mimic upper duct CCAs but

Figure 7 Shown is Bismuth type II cholangiocarcinoma. The right and left hepatic ducts are dilated (*upper arrows*), whereas the common hepatic duct is normal sized.

consist of chronic inflammatory cells and fibrous material. One distinguishing characteristic is that they do not involve blood vessels. Even today, they are very difficult to distinguish from cancers before pathologic examination of a resected specimen. Benign inflammatory tumors appear to occur most frequently in extrahepatic upper ducts, but they also occur intrahepatically and, less commonly, in lower ducts.

Gallbladder cancer may invade the porta hepatis and appear as a CCA, especially on ERCP. Gallstones are usually present. Axial imaging usually shows thickening of the gallbladder wall or the presence of a mass involving the infundibulum. Mirizzi syndrome is another cause of a focal stricture of the middle or upper bile duct. This syndrome results from compression of the bile duct by a large gallstone in the infundibulum and is usually associated with severe inflammation of the gallbladder and the characteristic signs and symptoms of acute cholecystitis. The duct is typically bowed to the left rather than focally narrowed, as in cancer. Iatrogenic causes should be considered if the patient has had a cholecystectomy. On occasion, a stricture appears years after the operation. In these cases, the probable cause of the stricture is ischemic injury to the bile duct. The presence of clips close to or indenting the duct is a clue that such injury is a possibility. Choledocholithiasis may also cause strictures, especially if cholangitis has occurred. Strictures are also frequent with recurrent pyogenic (oriental) cholangitis. Other rare tumors of the bile duct (e.g., neuroendocrine tumors) may mimic cholangiocarcinoma.

Surgical staging Often the first axial imaging test reveals only the presence of intrahepatic bile duct dilatation, which stops abruptly as the ducts merge in the hepatic hilum. This finding, however, leads to MRI or CT aimed at providing high-quality cholangiograms and angiograms of the hepatic arteries and the portal veins. Surgical staging of hilar CCA, unlike that of lower duct CCA, requires exact knowledge of the macroscopic upper extent of the tumor in the bile duct. Furthermore, invasion of hepatic arteries and portal veins is common and frequently affects resectability. Thus, surgical staging also requires accurate determination of the extent of

hepatic arterial or portal venous invasion and assessment of the degree of atrophy.

Bismuth type IV tumors are not resectable, except by liver transplantation. Type I through III tumors are resectable provided that the main portal vein and the proper hepatic artery, as well as the portal vein and the hepatic artery to the side of the liver to be retained, are not invaded by tumor and that the side to be retained is not atrophic. Involvement of the main portal vein or the hepatic artery is a relative rather than an absolute contraindication; lesser degrees of involvement can be handled by means of vascular resection and reconstruction in specialized centers. Unusual combinations of events may preclude resection (e.g., atrophy on one side of the liver and invasion of the hepatic artery supplying the other side, or invasion of the portal vein to one side and the bile duct on the other side to the level of the secondary biliary branches).

MRI (with MRCP and magnetic resonance angiography [MRA]) or CT with the latest generation of scanners can provide complete information regarding the extent of bile duct involvement and the degree of vascular invasion. Doppler ultrasonography is also excellent for evaluating vascular invasion. In our experience, the combination of these two investigations usually provides more useful staging information than either individually. Both are dependent on highly experienced radiologists. ERCP may be used for additional assessment of the extent of the tumor on the side to be retained if a stent on that side is deemed necessary. The use of percutaneous cholangiography is controversial, the main concern being the risk of tumor seeding along the tube, into the peritoneal cavity, and onto the surface of the liver or the abdominal wall. Nevertheless, this procedure is used extensively in Japan, where surgeons have considerable experience with selective decompression of parts of the liver as a preoperative strategy.²⁷

Assessment of distant metastases is achieved by means of axial imaging of the chest and the abdomen. Staging laparoscopy identifies 10 to 15% of cancers that are unresectable because of peritoneal or liver metastases. FDG-PET identifies about 15% of patients with distant metastases. At present, neither of these tests is routinely employed in this setting. Staging laparoscopy has provided a good yield of unresectable cases in some studies but not in others.

Management *Preoperative preparation* Unlike cancers of the lower bile duct, cancers of the upper bile duct usually necessitate major liver resection [see 5:22 *Procedures for Benign and Malignant Biliary Tract Disease*]. Consequently, it has been argued that the risk of postoperative hepatic failure may be lowered by preoperative decompression, especially decompression of the side to be retained, which has the dual purpose of allowing that side to recover function and of actually encouraging hypertrophy. On the other hand, stents may introduce bacteria and cause cholangitis. As noted (see above), selective percutaneous decompression is an accepted strategy in Japan; often multiple stents are inserted.²⁸

A reasonable strategy is to proceed to operation if (1) the patient is relatively young (< 70 years), (2) there are no serious comorbid conditions, (3) the jaundice has been present for less than 4 weeks, (4) the serum bilirubin concentration is lower than 10 mg/dL, (5) the future remnant liver will include more than 35% of the total liver mass, and (6) the patient has not undergone biliary instrumentation (which

always contaminates the obstructed biliary tract). In all other cases, we routinely decompress the side of the liver to be retained and wait until the serum bilirubin concentration falls to 3 mg/dL. When the future remnant liver will include less than 30 to 35% of the total liver mass, portal vein embolization (PVE) of the side to be resected may be performed to induce hypertrophy of the remnant. Because resection for hilar CCA is a major procedure in a somewhat compromised liver, it is contraindicated in patients who are in poor general condition or who have major organ dysfunction.

Rationale for surgery Patients with upper duct CCA are candidates for resection if they have no distant metastases (including intrahepatic metastases) and if the tumor can be removed in its entirety by means of bile duct resection [see 5:22 *Procedures for Benign and Malignant Biliary Tract Disease*] combined with liver resection [see 5:23 *Hepatic Resection*]. The goal of resection of upper duct CCA is to achieve clear resection margins by removing the tumor, the portal and celiac lymph nodes, the side of the liver in which the ductal involvement is greater (via hemihepatectomy or trisectionectomy), and the caudate lobe. (The caudate lobe is resected because cholangiocarcinomas tend to invade along the short caudate bile ducts, which enter the posterior surfaces of the main right and left bile ducts at the bifurcation of the common hepatic duct.) Recently, some surgeons have extended the portal dissection to include the portal vein when the right side of the liver is to be resected.

Table 5 American Joint Committee on Cancer TNM Clinical Classification of Gallbladder Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	Tis	Carcinoma in situ
	T1	Tumor invades lamina propria or muscle layer
	T1a	Tumor invades lamina propria
	T1b	Tumor invades muscle layer
	T2	Tumor invades perimuscular connective tissue; no extension beyond serosa into liver
	T3	Tumor perforates serosa (visceral peritoneum) and/or directly invades one adjacent organ or structure such as the stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts
	T4	Tumor extends > 2 cm into liver or invades two or more adjacent organs (e.g., duodenum, colon, pancreas, omentum, or extrahepatic bile ducts)
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

This provides a wide resection zone and removes an area that is frequently involved by microscopic tumor.²⁸

Liver transplantation has been used successfully to manage Bismuth type IV tumors and is usually performed after neoadjuvant chemoradiation therapy and staging laparotomy in highly selected patients.²⁹ Liver transplantation for Bismuth tumors of lesser Bismuth grades is highly controversial.

Gallbladder Cancer

The incidence of gallbladder cancer in the United States is about 9,000 cases a year. This cancer almost always arises in patients with preexisting gallstones and is most often seen in elderly patients. Like ductal adenocarcinoma of the pancreas, it is highly malignant and tends to spread at an early stage to lymph nodes, to peritoneal surfaces, and to areas of the liver distant from the gallbladder fossa. AJCC staging criteria are helpful for planning management of this cancer [see Table 5 and Table 6].

Clinical Evaluation

Gallbladder cancer is discovered either incidentally during performance of cholecystectomy for symptomatic cholelithiasis or when the tumor causes symptoms related to invasion of the bile duct or to the effects of metastatic disease. In early stages of the disease in which the tumor is confined to the wall of the gallbladder, the symptoms are usually those of the associated stones—that is, the patient has biliary colic, and the cancer is silent. In later stages of disease, jaundice, weight loss, a palpable right upper quadrant mass, hepatomegaly, or ascites may develop. Jaundice occurs in about 50% of patients. It is a poor prognostic sign because it signifies extension of the tumor beyond the gallbladder and obstruction of the extrahepatic bile ducts. Consequently, most gallbladder cancer patients with jaundice have unresectable tumors. Because the signs and symptoms of gallbladder cancer are nonspecific, delays in diagnosis are common. As a result, most gallbladder cancers are not diagnosed until they have reached stage III or IV; thus, most of these aggressive tumors are unresectable at presentation, even when the patient is not jaundiced.

Investigative Studies

Laboratory tests In stages I and II, LFTs usually yield normal results. In later stages, laboratory test abnormalities may be noted that are not diagnostic but are consistent with bile duct obstruction. Elevated alkaline phosphatase and bilirubin levels are common. An elevation in the serum CA 19-9 concentration is the most helpful diagnostic indicator.

Table 6 American Joint Committee on Cancer Staging System for Gallbladder Cancer

Stage	T	N	M
0	Tis	N0	M0
IA	T1	N0	M0
IB	T2	N0	M0
IIA	T3	N0	M0
IIB	T1, T2, T3	N1	M0
III	T4	Any N	M0
IVB	Any T	Any N	M1

Imaging Because gallbladder cancer is most curable in its early stages and because the symptoms in those stages are those of cholelithiasis, it is important for surgeons to be aware of subtle signs of gallbladder cancer that are occasionally present on sonograms. These signs include asymmetrical thickening of the gallbladder wall, thickening of the wall in a patient without a history of biliary colic, a mass projecting into the lumen, multiple masses or a fixed mass in the gallbladder, calcification of the gallbladder wall (so-called porcelain gallbladder), and an extracholecystic mass. Displacement of a stone to one side of the gallbladder should also be viewed with suspicion.

In later stages of disease, CT scans usually show a gallbladder mass with or without invasion of the liver or other adjacent organs. Obstruction of the bile duct produces the usual features associated with obstructive jaundice. Percutaneous CT-guided biopsy is a useful technique for confirming the diagnosis in patients with unresectable tumors.

Porcelain gallbladder is a premalignant condition, although there is some evidence that the incidence of cancer depends on the pattern of calcification: selective mucosal calcification apparently carries a significant risk of cancer, whereas diffuse intramural calcification does not.³⁰ It seems reasonable to resect only tumors with the former pattern, but whenever there is a question about the pattern of calcification, one should err on the side of resection.

Surgical Staging

Staging of gallbladder cancer requires knowledge of the extent of direct invasion into the liver and other adjacent organs and tissues (especially the bile duct, the portal veins, and the hepatic arteries). As in hilar CCA, this information may be obtained by means of MRCP and MRA or CT with the latest generation of scanners. Staging laparoscopy is very helpful in managing gallbladder cancer. As many as 50% of patients with this disease are found to have peritoneal or liver metastases on staging laparoscopy,⁸ and as with carcinoma of the body of the pancreas, no useful palliative measures can be undertaken at laparotomy.

Management

Rationale for surgery When early-stage gallbladder cancer is suspected on the basis of diagnostic imaging, open cholecystectomy, rather than laparoscopic cholecystectomy, is probably the procedure of choice [see 5:21 *Cholecystectomy and Common Bile Duct Exploration* and 5:22 *Procedures for Benign and Malignant Biliary Tract Disease*]. Intraoperatively, if there is no evidence of spread outside the gallbladder, we recommend performing an extraserosal cholecystectomy, in which the fibrous liver plate is excised along with the gallbladder so that bare liver is exposed. It is possible to perform an extraserosal resection laparoscopically; however, in our opinion, this should not be attempted, because gallbladder perforation and bile spillage are more common with the laparoscopic version of the procedure. The negative consequences of tumor implantation or incomplete excision far outweigh any benefit that a minimally invasive approach might confer.

The excised specimen should be inked and a frozen section obtained. If there is gallbladder cancer in the specimen but the resection margins are clear and the tumor is a T1 lesion (i.e., has not penetrated the muscularis), the procedure is considered complete in that lymph node metastases are uncommon

with T1 tumors (incidence < 10%). However, lymph node metastases are present in 50% of patients with T2 lesions (i.e., tumors that have invaded the muscularis). Therefore, if margins are positive or the tumor is a T2 lesion, resection of segments 4b and 5 of the liver and dissection of the portal and celiac lymph nodes are recommended. Resection of the extrahepatic bile duct and hepaticojunostomy may be needed in some cases to obtain a complete node clearance, but this is being done less frequently as experience with portal node clearance has been obtained. If it is already clear at the commencement of the operation that the tumor is T2, one should proceed directly to liver, lymph node, and bile duct resection.

In more advanced stages of disease (T3 and T4), the aim is still excision with clear margins and resection of portal and celiac lymph nodes. To obtain clear local margins with these tumors, in addition to what is required for T2 tumors, more extensive hepatic resections—up to a trisectionectomy (resection of segments 4 through 8) [see *Liver Cancer, Anatomic Considerations, below*]³¹—may be necessary, as well as resection of adjacent organs.

Incidentally discovered gallbladder cancer Gallbladder cancer may be an incidental finding at laparoscopic cholecystectomy, as it has been at open cholecystectomy. The incidence of this finding ranges from 0.3 to 1.0%. A concern that has arisen in the current era, in which the laparoscopic approach to cholecystectomy is dominant, is the risk of port-site implantation of tumor. Port-site implantation is the result of contact between the malignancy and the tissues surrounding the port site at the time of gallbladder extraction. Therefore, when evidence of gallbladder wall thickening is noted intraoperatively, the gallbladder should be extracted in a sac. The gallbladder should be inspected at the time of extraction, and any questionable areas should undergo biopsy.

If a gallbladder cancer is discovered at the time of operation, it should be treated without delay according to the principles stated earlier (i.e., depending on whether the margins on the excised gallbladder are clear and on the T stage of the tumor). From an oncologic viewpoint, it would seem ideal to resect the tissue around all trocar port sites. From a technical viewpoint, however, it would be very difficult and impractical to excise the full thickness of the abdominal wall circumferentially around four port sites, especially because the tract of the port site often is not at a 90° angle to the abdominal wall. If the gallbladder was extracted through a port site without having been placed into a bag, it is reasonable to attempt excision of that one port site.

Sometimes cancer is suspected, but frozen-section examination is inconclusive, and the definitive diagnosis of cancer is not made until the early postoperative period. More often, cancer is not suspected intraoperatively, and the diagnosis is made only when permanent sections of the gallbladder are examined. In these situations, patients with completely excised T1 lesions require no further therapy, and patients with higher-stage lesions should undergo reoperation in accordance with the principles outlined earlier (see above). Other appropriate reasons for not performing the additional surgery at the time of the cholecystectomy are (1) the desire to discuss the management scheme with the patient and (2) a lack of experience with the procedure for T2 tumors. Not infrequently, patients are referred to hepatic-pancreatic-biliary centers 10 to 14 days after surgery, which is an

inopportune time for reoperation, especially if the first procedure was difficult. Surgery may then be delayed for 3 to 4 weeks. We restage patients with abdominal CT scans when they are referred with this diagnosis, and it is not unusual to find hepatic metastases when this is done. The survival rate is much higher after radical resection than after cholecystectomy, even when cholecystectomy was the first procedure.³²

Gallbladder polyps Benign gallbladder polyps may be adenomas or more commonly a focal form of cholesterolosis. Multiple polyps are most often due to cholesterolosis. Gallbladder polyps are discovered incidentally on ultrasonograms or CT scans or are diagnosed when they cause biliary colic. They may be malignant but are rarely so when less than 1 cm in diameter, especially when they are multiple. Most gallbladder polyps are less than 0.5 cm in diameter; these are almost always benign cholesterol polyps and may be followed if they are not giving rise to symptoms. Single polyps between 0.5 and 1 cm in diameter should probably be removed by means of cholecystectomy. Multiple asymptomatic polyps in this size range should be followed because they are more likely to be due to cholesterolosis. About one quarter of all single gallbladder polyps more than 1 cm in diameter are malignant, and such polyps should be treated as malignant as a matter of policy. Almost all polyps

more than 1.8 cm in diameter are malignant.³³ Gallbladder sludge and stones may be mistaken for polyps. They are differentiated by using Doppler ultrasonography to determine if the lesion has internal blood flow. If internal blood flow is absent, the lesion is unlikely to be a polyp.

Liver Cancer

ANATOMIC CONSIDERATIONS

A long-standing problem in discussing any surgical liver disease, especially liver cancer, has been the confusing terminology applied to liver anatomy and the various hepatic resections. Fortunately, a lucid and cogent terminology has emerged that is sanctioned by both the International Hepato-Pancreato-Biliary Association (IHPBA) and the American Hepato-Pancreato-Biliary Association (AHPBA).³¹ This terminology has been widely adopted around the world and translated into many languages. It may be briefly summarized as follows.

The fundamental principle is that the anatomic divisions of the liver are based on vascular and biliary anatomy rather than on surface markings [see Figure 8]. This is an important point because surgical resection is a process of isolating specific liver volumes serviced by specific vascular and biliary

Figure 8 Illustrated are the anatomic divisions of the liver according to IHPBA/AHPBA-sanctioned terminology, including first-order divisions (hemilivers), second-order divisions (sections), and third-order divisions (segments).

structures. The anatomic ramifications of the hepatic artery and the bile duct are regular and virtually identical. Liver anatomy is best understood by first following these structures through a series of orderly divisions. The branching of the portal vein on the right side is similar to that of the bile duct and the hepatic artery, but its branching on the left side is unusual as a result of the need in the fetus that the umbilical portion of the portal vein acts as a conduit carrying blood in the reverse direction to that postnatally.

The first-order division of the proper hepatic artery and the common hepatic duct into the right and left hepatic arteries and the right and left hepatic ducts, respectively, results in

division of the liver into two parts (or volumes), referred to as the right and left hemilivers (or the right and left livers) [see *Figure 8 and Table 7*]. In this system of terminology, the term “lobe” is never used to denote a hemiliver, because it bears no relation to the internal vascular anatomy. The right hepatic artery supplies the right hemiliver, and the left hepatic artery supplies the left hemiliver. The right and left hepatic ducts drain the corresponding hemilivers. The plane between these two zones of vascular supply is called a watershed. The border or watershed of the first-order division is a plane that intersects the gallbladder fossa and the fossa for the inferior vena cava and is called “the midplane of the liver.”

Table 7 Brisbane 2000 Terminology for Hepatic Anatomy and Resections of the IHPBA

Level of Division	Preferred Anatomic Term	Corresponding Couinaud Segments (Sg)	Preferred Term for Surgical Resection*	Comments
First order (hemiliver)	Right hemiliver or Right liver	Sg 5–8 ($\pm$ caudate lobe)	Right hepatectomy or Right hemihepatectomy (stipulate $\pm$ caudate lobe)	The border or watershed separating the two hemilivers is a plane that intersects the gallbladder fossa and the IVC fossa; this plane is referred to as the midplane of the liver
	Left hemiliver or Left liver	Sg 2–4 ($\pm$ caudate lobe)	Left hepatectomy or Left hemihepatectomy (stipulate caudate lobe)	
Second order (section)	Right anterior section	Sg 5, 8	Right anterior sectionectomy	The borders or watersheds separating the sections within the hemilivers are planes referred to as the right intersectional plane (for which there is no surface marking) and the left intersectional plane (which passes through the umbilical fissure and the attachment of the falciform ligament)
	Right posterior section	Sg 6, 7	Right posterior sectionectomy	
	Left medial section	Sg 4	Left medial sectionectomy	
	Left lateral section	Sg 2, 3	Left lateral sectionectomy	
	—	Sg 4–8 ($\pm$ caudate lobe)	Right trisectionectomy (preferred) or Extended right hepatectomy or Extended right hemihepatectomy (stipulate $\pm$ caudate lobe)	
	—	Sg 2, 3, 4, 5, 8 ($\pm$ caudate lobe)	Left trisectionectomy (preferred) or Extended left hepatectomy or Extended left hemihepatectomy (stipulate $\pm$ caudate lobe)	
Third order (segment)	Segments 1–8	Any Sg	Segmentectomy (stipulate Sg—e.g., segmentectomy 7)	The borders or watersheds of the segments are planes referred to as the intersegmental planes
	Two contiguous segments	Any two Sg in continuity	Bisegmentectomy (stipulate Sg—e.g., bisegmentectomy 7, 8)	

IHPBA = International Hepato-Pancreato-Biliary Association; IVC = inferior vena cava.

*It is also permissible to refer to any resection in terms of its third-order components. Thus, a left hemihepatectomy may be referred to as a resection Sg 2–4 (or 1–4).

The second-order division divides each of the hemilivers into two parts [see *Figure 8 and Table 7*], referred to as sections. The right hemiliver comprises the right anterior section and the right posterior section. These sections are supplied by a right anterior sectional hepatic artery and a right posterior sectional hepatic artery and are drained by a right anterior sectional hepatic duct and a right posterior sectional hepatic duct. The left hemiliver comprises the left medial section and the left lateral section. These sections are supplied by a left medial sectional hepatic artery and a left lateral sectional hepatic artery and are drained by a left medial sectional hepatic duct and a left lateral sectional hepatic duct.

The third-order division divides the liver into nine segments, each of which has its own segmental artery and bile duct [see *Figure 8 and Table 7*]. The caudate lobe, a unique portion of the liver that is separate from the right and left hemilivers, is also referred to as segment 1. The left lateral section comprises segments 2 and 3; the left medial section comprises segment 4 (which is sometimes further divided into segments 4a and 4b); the right anterior section comprises segments 5 and 8; and the right posterior section comprises segments 6 and 7.

PRIMARY CANCERS

Hepatocellular Cancer

Hepatocellular cancer (HCC), or hepatoma, is the fifth most common cancer in the world. About 90% of cases arise in patients with chronic liver disease, especially when the disease has progressed to cirrhosis. Although any condition that produces cirrhosis may lead to HCC, the most common cause is viral hepatitis. In the United States, some 3 million people are infected with hepatitis C virus (HCV), and more than 1 million people have liver disease associated with hepatitis B virus (HBV). HCV infection is much more likely

Table 8 American Joint Committee on Cancer TNM Clinical Classification of Adult Primary Liver Cancer

Primary tumor (T)	TX	Primary tumor cannot be assessed
	T0	No evidence of primary tumor
	T1	Solitary tumor without vascular invasion
	T2	Solitary tumor with vascular invasion; multiple tumors, none > 5 cm in greatest dimension
	T3	Multiple tumors > 5 cm in greatest dimension or tumor involving major branch of portal or hepatic vein
	T4	Tumor or tumors with direct invasion of adjacent organs (other than gallbladder) or visceral peritoneum
Regional lymph nodes (N)	NX	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis
	N1	Regional lymph node metastasis
Distant metastasis (M)	MX	Distant metastasis cannot be assessed
	M0	No distant metastasis
	M1	Distant metastasis

to lead to HCC than HBV infection is. AJCC staging criteria are useful for planning the management of liver cancer [see *Table 8 and Table 9*].

Clinical evaluation The usual presentation of sporadic HCC consists of pain, mass, and systemic symptoms of cancer, although the disease may also be discovered incidentally. HCC occurring as a complication of liver disease may present similarly, but it is often manifested first as a deterioration of liver function with the onset of jaundice, ascites, or encephalopathy.

Investigative studies Screening programs are employed in high-risk populations. These programs, which use α -fetoprotein (AFP) levels and ultrasonographic examination of the liver to detect early HCC, may detect asymptomatic tumors.

The diagnosis of sporadic HCC is based on elevation of AFP levels (an indicator with 50 to 60% sensitivity) and the presence of a hepatic mass on axial images. HCCs typically demonstrate hypervascularity, which is best seen on arterial-phase images [see *Figure 9*]. A pseudocapsule is often visualized, which is best seen on portal venous-phase images. MRI has been found to be more sensitive than CT in the detection of HCC. The characteristic findings are those of a hypervascular tumor on the arterial phase with washout of contrast in the venous phase. These findings also help differentiate HCC from cirrhotic

Figure 9 Computed tomographic scan shows a hypervascular hepatocellular carcinoma of the left liver.

nodules, which typically do not show washout. Multifocality is also common in HCC, unlike other hepatic neoplasms. Routine biopsy is not indicated in patients with a characteristic mass, those who have a mass and an elevated AFP level, or those who are symptomatic and require treatment for pain. HCC may be very well differentiated and difficult to distinguish from hepatic adenoma and focal nodular hyperplasia on biopsy. It may also be hard to distinguish from cirrhotic nodules. Biopsy is associated with a small risk of bleeding or tumor seeding.

Surgical staging Staging of sporadic HCC requires axial imaging of the abdomen and imaging of the chest. FDG-PET scanning is only marginally useful: HCCs are typically well differentiated, and, as a result, only 50% of the tumors are visualized. Staging laparoscopy is helpful: additional tumors are found in about 15% of patients.³⁴

Staging also requires evaluation of the extent of liver disease. The Child-Pugh classification is used to determine operability. With few exceptions, resection is limited to Child-Pugh class A patients with near-normal bilirubin levels (< 1.5 mg/dL), a normal or marginally raised prothrombin time, and no or minimal portal hypertension. The extent of resection must be tailored to the severity of the liver disease. For instance, resection of more than two segments is limited to patients with normal liver function. Too extensive resection puts the patients at risk for liver failure in the postoperative period. In Japan and China, indocyanine green clearance is used in Child-Pugh class A patients to determine the possible extent of resection.

Management *Rationale for surgery* The rationale for surgery is clear in patients without liver disease or in Child-Pugh class B or C patients with chronic liver disease. The rationale for surgery in Child-Pugh class A patients, however, remains controversial.

Partial liver resection [*see 5:23 Hepatic Resection*] is the procedure of choice for sporadic HCC in patients with normal livers. In Child-Pugh class B or C patients with chronic liver disease, liver resection can be hazardous, and orthotopic liver transplantation (OLT) is the procedure of choice. To justify the use of donor organs, however, it is necessary to select patients with HCC so that the long-term outcome of OLT for HCC is similar to that of OLT for benign conditions. To achieve this goal, OLT is restricted to patients with a single tumor less than 5 cm in diameter or to patients with as many as three tumors, none of which are more than 3 cm in diameter (the Milan criteria). These criteria have been shown to be associated with OLT outcomes comparable to those for benign conditions.³⁵

In Child-Pugh class A patients with liver disease, hepatic resection and OLT are options if the Milan criteria are met. The optimal therapeutic approach in this situation has been the subject of considerable debate, with proponents arguing for one of two strategies—namely, (1) primary OLT or (2) resection followed by OLT if HCC recurs,^{36,37} provided that the patients still meet the criteria for OLT (so-called salvage OLT). A complete discussion of this controversy is beyond the scope of this chapter. Currently, it would seem that the best strategy in patients who meet the criteria for OLT is to perform resection followed by transplantation if disease recurs.^{36,37} There is a trend toward liberalizing the OLT criteria to include single tumors 6 or 7 cm in diameter, especially if the source of the organ is a living donor.

When OLT is to be performed, it is important that the waiting time be short; these tumors progress over a timescale

of a few months, and when viewed on an intention-to-treat basis, the results of OLT deteriorate significantly if the waiting time is long.³⁸ In the United States, this concern has been dealt with by the introduction of the Model for End-stage Liver Disease (MELD) scoring system, which gives priority to recipients with HCC. It is common in the United States—and even more usual in countries with longer waiting times—to inhibit the growth of the HCC with various bridging-to-transplantation strategies during the waiting period for OLT. Such strategies include systemic chemotherapy, local treatments (e.g., radio-frequency [RF] ablation and alcohol injection), transarterial chemoembolization (TACE), and even resection of the HCC (so-called bridge resection). TACE may also be used to downsize tumors so that they meet transplant criteria.

In patients with nondiseased livers, the extent of resection depends on the size and position of the tumor. As much as 75% of the liver may be safely excised when normal liver function is present. The size of the future hepatic remnant may be determined by means of imaging. PVE of the side of the liver to be resected may be performed preoperatively to increase the size of the future remnant. It may also be used for this purpose in patients with liver disease. In these patients, PVE functions as a test of the liver's ability to regenerate. Failure to respond to PVE is itself a contraindication to surgery in patients with chronic liver disease.

As a rule, liver resections for HCC should be anatomic [*see 5:23 Hepatic Resection*]. Recurrence rates are higher with nonanatomic resections because HCCs grow along portal veins and metastasize locally within segments, sections, or hemilivers, depending on how far they reach back along the portal veins. When a nonanatomic resection is performed, the resection margins should be 2 cm or greater. When HCC reaches the main portal vein, resection is generally contraindicated; the results are very poor in this situation.

Intrahepatic Cholangiocarcinoma

Clinical evaluation Intrahepatic CCAs arise from intrahepatic bile ducts. The three phenotypic types, MF, PI, and IG, are described above. The MF type is by far the most common. Intrahepatic CCA tumor usually occurs in normal livers. The presentation is similar to that of sporadic HCC.

Investigative studies The appearance of intrahepatic CCA on CT is suggestive of a secondary tumor [*see Figure 10*]. Unlike HCC, diagnosis of intrahepatic CCA often requires biopsy, which reveals an adenocarcinoma that is indistinguishable from a hepatic metastasis. Special stains may be helpful in differentiating this tumor from a true secondary malignancy, but the differentiation is rarely certain. An elevated CA 19-9 concentration is strongly suggestive of this diagnosis if it is higher than 100 U/mL. To make the diagnosis of intrahepatic CCA, primary tumors in other sites must be excluded by means of axial imaging of the chest, the abdomen, and the pelvis; upper and lower GI endoscopy; and mammography. FDG-PET scanning is another helpful method by which an extrahepatic primary tumor may be identified.

Surgical staging FDG-PET scanning appears to be a promising staging tool for identifying portal lymph node and distant metastases when the primary tumor is actually an intrahepatic CCA. Portal lymph node metastases are a relative contraindication to resection in patients with MF tumors; the results of resection in this situation are poor. Left-side tumors

Figure 10 Computed tomographic scan shows a mass-forming intrahepatic cholangiocarcinoma.

may metastasize to lymph nodes at the cardia of the stomach and along the lesser curvature or to the mediastinum.

Management The considerations related to resection for intrahepatic CCA are similar to those for sporadic HCC (see above). Liver transplantation generally is not performed for this tumor, because of the typically poor results.

SECONDARY CANCERS

Colorectal Metastases

Clinical evaluation and investigative studies About 50% of the 150,000 patients who are diagnosed with colorectal cancer annually in the United States either have or will

have liver metastases. About 10% of patients with these colorectal metastases (CRMs) are eligible for liver resection. CRMs may be diagnosed either at the time of treatment of the primary colorectal cancer (synchronous tumors) or at a later stage (metachronous tumors).

Synchronous tumors are diagnosed by means of either preoperative CT scanning [see Figure 11] or intraoperative palpation. LFTs may show elevations (especially of the serum alkaline phosphatase level), but these results are not specific. CEA levels are not helpful as long as the primary tumor is in place. Metachronous tumors are most often diagnosed in the course of a postcolectomy surveillance program, either by imaging the liver with CT or FDG-PET scans or by detecting a rise in the CEA level. When synchronous metastases are discovered preoperatively, a FDG-PET scan should be done to complete the staging.

Surgical staging In about 25% of patients, FDG-PET scans change management as a result of detecting unsuspected extrahepatic or intrahepatic disease. Sometimes it demonstrates that apparent metastases are actually benign lesions. Second primary tumors are not uncommon in patients with metachronous lesions; accordingly, such patients should also be staged by means of colonoscopy, if this procedure was not done in the preceding 6 months, as well as FDG-PET scanning. Staging laparoscopy adds little to staging if an FDG-PET scan has been done.

Intraoperative staging consists of careful palpation of intra-abdominal structures, including hepatic and portal venous lymph nodes. In patients with metachronous lesions, however, palpation of the entire abdomen may be limited by adhesions from previous operations. IOUS of the liver may also detect unsuspected lesions, although this is less likely if the patient has already been staged by means of FDG-PET.

The main value of FDG-PET in this setting is its ability to discover unsuspected extrahepatic disease. In so doing, it helps eliminate futile hepatic resections. If a patient

Figure 11 Colorectal metastasis. (a) Computed tomography shows a single large tumor in right hemiliver; (b) is the resected specimen.

with extrahepatic disease is treated with hepatic resection, a “recurrence” is inevitable. Elimination of pointless resections has a positive effect on survival: a 2004 study from our institution found that the overall 5-year survival rate after FDG-PET was about 60%, compared with 40% after conventional imaging.³⁹ Furthermore, after FDG-PET scanning has been done, the most important prognostic factors determining long-term outcome are the grade of the primary colorectal tumor and whether the primary tumor had metastasized to lymph nodes.⁴⁰ FDG-PET-scanned patients with poorly differentiated primary tumors do poorly in terms of overall survival after hepatic resection.³⁹ In recent years, standard PET scanners have been replaced with CT-PET scanners, which fuse the images and provide superior diagnosis and staging. For planning surgical extirpation, however, the level of detail provided by high-quality contrast-enhanced CT or MRI is also required.

Management *Rationale for surgery* The classic criteria that determined eligibility for resection are (1) that the primary tumor has been or can be completely resected, (2) that (with uncommon exceptions) there is no extrahepatic tumor (other than the primary tumor), and (3) that it is possible to resect all tumors in the liver while leaving enough of a hepatic remnant to ensure that hepatic failure does not develop postoperatively. The considerations governing the extent of the resection and the use of PVE are similar to those for sporadic HCC.

Treatment of multiple tumors is much more common with CRMs than with HCC. However, nonanatomic resections are as effective as anatomic resections as long as the resection margin is microscopically clear. The traditional view has been that resection margins of 1 cm are mandatory and lesser margins lead to poorer results. This view has been challenged in several studies that claim that margins as narrow as 1 mm are satisfactory and are probably as effective as traditional margins provided that they are free of microscopic and gross cancer. This issue must be considered to still be unsettled, and, certainly, 1 cm margins should be the goal whenever feasible. When close margins are expected, transection of the liver with a saline-linked RF ablation device may be useful in that this device leaves a margin of devitalized tissue in the patient and in the specimen.⁴¹ When the margin is very close, it may be extended by painting the cut surface of the hepatic remnant with the RF device.

Synchronous resection of the primary tumor and the liver metastases has proved to be safe⁴² and is desired by many patients. The decision to proceed with hepatic resection should not be made until resection of the primary tumor has been completed and it has been determined that the margins are clear and the patient is stable. Some patients with a small number of lung lesions in addition to liver lesions have been cured by resection.

The classic criteria for resection have been challenged and extended by new surgical approaches and the advent of much improved chemotherapy, including oxaliplatin and irinotecan, as well as the targeted monoclonal antibodies bevacizumab and cetuximab. These agents have demonstrated the ability to downsize colorectal tumors both in the liver and at extrahepatic sites. Thus, many formerly unresectable patients can now have liver resection after downsizing with chemotherapy. It is generally agreed that the best time for surgery is when the size and the position of tumors are such that liver resection can be done safely.⁴³ Continuing chemotherapy

until maximal effect is undesirable because irinotecan has been associated with the development of steatohepatitis⁴⁴ and oxaliplatin with endotheliolitis.⁴⁵ These injuries can make liver resection hazardous. Furthermore, continued downsizing may make tumors difficult to locate. This is important because although tumors may show a complete radiologic response on CT and FDG-PET scans, this is infrequently associated with a complete pathologic response. The ability to resect multiple large tumors from the liver has been enhanced by PVE and two-stage hepatectomy. In this approach, one side of the liver is cleared of tumor and the portal vein on the other side is occluded. At a second stage, the atrophied side containing the bulk of the disease (usually the right hemiliver) is excised.

Extrahepatic disease in patients with hepatic metastases Good results have been obtained in patients with recurrent disease in the primary colorectal site and liver metastases, as well as liver and lung metastases.⁴⁶ With the advent of the new chemotherapy, it may be warranted to extend this approach to patients with liver and portal lymph node metastases but not with positive lymph nodes in the celiac or para-aortic regions.⁴⁷ Peritoneal metastases have been treated successfully by resection combined with hyperthermic intraperitoneal chemotherapy. Whether this approach combined with liver resection would be effective in patients with liver and peritoneal metastases is uncertain. Its application seems warranted in selected well-followed cases.

Ablation of colorectal metastases In situ destruction of tumors with cryotherapy or RF ablation may expand the surgeon's ability to eradicate CRMs localized to the liver.⁴⁸ RF ablation has largely supplanted cryotherapy in this context as a result of its lower incidence of complications and greater ease of use. Ablation may be used either as an adjunct to operative management or as the sole treatment when there are many metastases (but usually < 10). The efficacy of RF ablation as an adjunct to surgery remains to be determined. It is doubtful, however, that using this modality alone to eradicate multiple lesions will improve overall survival significantly because the tumor biology in such cases is likely to be that of an aggressive tumor. Recent data suggest that the preceding statement is correct.⁴⁹ FDG-PET scans should be performed in all such patients; the likelihood of discovering extrahepatic tumors increases as the number of hepatic tumors increases.³⁹

RF ablation is not recommended for treatment of resectable metastases: it is not approved for this purpose, and using it in this way would mean substituting an unproven therapy of unknown efficacy for a proven therapy of known value. Again, based on recent publications, it is highly likely that RF ablation results in poorer long-term survival than liver resection.⁴⁸ If a consenting patient with resectable metastases nevertheless insists on this less invasive therapy, the surgeon should document that the preceding considerations have been explained. RF ablation may be applied by means of open, laparoscopic, or percutaneous methods. There is good reason to believe that targeting ability is degraded as one moves to less invasive methods. This consideration should also be explained to patients, although, undoubtedly, there are some patients who, because of comorbid conditions, are candidates only for percutaneous or laparoscopic approaches.

Neuroendocrine Metastases

Neuroendocrine metastases are characteristically slow growing. Some are functional, especially if they arise from the ileum; metastatic liver disease from this source may produce carcinoid syndrome. ¹¹¹In-pentetreotide imaging (OctreoScan, Mallinckrodt Inc., Hazelwood, Missouri) provides staging information comparable to that provided by FDG-PET in patients with CRMs.

The aims of surgical treatment are (1) to eradicate the cancer and (2) to reduce hormonal symptoms. The considerations regarding tumor eradication for neuroendocrine metastases are similar to those for CRMs—that is, resection should be performed if all cancer can be removed and no extrahepatic cancer is detectable. In highly symptomatic patients in whom conservative therapy with octreotide has failed, debulking the tumor by means of either chemoembolization or surgery may provide relief. The former is more suitable for patients with multiple small, diffuse metastases, whereas the latter is preferred for patients with large localized tumors. RF ablation may also be employed, either combined with surgical treatment or alone; this is an excellent use of this procedure in that the aim is cytoreduction rather than eradication. Debulking tumors in asymptomatic patients with the intention of extending survival is controversial. It is not recommended when more than 10% of the tumor will remain.

Noncolorectal, Non-neuroendocrine Metastases

Occasionally, liver metastases from other primary sites behave like CRMs in that they are localized to part of the liver in the absence of extrahepatic disease. Such patients can be managed according to the same approach employed for CRMs, although the outcome is somewhat less satisfactory. Tumors that have been treated in this way with acceptable results include breast cancers, renal cell cancers, gastric cancers, acinar cell cancers of the pancreas, and ovarian cancers. Liver resection for more aggressive malignancies (e.g., metastases from gallbladder cancer and pancreatic ductal adenocarcinomas) can be expected to yield very poor results.

INCIDENTALLY DISCOVERED ASYMPTOMATIC HEPATIC MASS

Now that transaxial imaging of the abdomen is commonly performed for a variety of complaints, the problem of the incidentally discovered asymptomatic hepatic mass is being encountered with increased frequency. Generally, cysts are

easily distinguished from solid tumors; the main diagnostic issue is differentiation of the various solid lesions.

The differential diagnosis of the benign solid hepatic mass includes hepatic adenoma, focal nodular hyperplasia (FNH), focal fatty infiltration, cavernous hemangioma, and other rare neoplasms (e.g., mesenchymal hamartoma and teratoma)—all of which must be distinguished not only from one another but also from malignant tumors. In the past, several diagnostic tests (e.g., ultrasonography, CT, sulfur colloid scanning, and angiography) were used to differentiate these neoplasms. Currently, our usual practice is to perform MRI with gadolinium contrast enhancement, which generally allows accurate differentiation among benign tumors with a single test. Cavernous hemangiomas are usually easy to distinguish because they have a characteristic appearance on MRI (hypointense on T₁-weighted images, very intense on T₂-weighted images, and filling in from the periphery with gadolinium injection); if they are asymptomatic, they need not be resected. It is important to distinguish asymptomatic FNHs from hepatic adenomas: whereas resection is recommended for adenomas because of their potential for hemorrhage or malignant degeneration, asymptomatic FNHs can safely be observed. An FNH is nearly isointense on T₁- and T₂-weighted images; it shows slightly more enhancement than normal liver parenchyma in the early phase after contrast injection and then becomes isointense. A central scar is often, but not always, seen. Conversely, a hepatic adenoma exhibits strong early-phase enhancement with contrast administration and tends to be hyperintense on T₁-weighted images.

Given that a symptomatic hepatic mass is usually treated with resection, preoperative biopsy for tissue diagnosis is rarely necessary or desirable. Modern noninvasive radiologic tests, in conjunction with a careful patient history, are often quite accurate in predicting histologic diagnosis. Biopsy of hepatic lesions should not be performed indiscriminately, because there is a small risk of complications or tumor tracking and because biopsy results often do not change management. As a rule, biopsies should be performed when definitive surgical intervention is not planned and when pathologic confirmation is necessary for institution of nonsurgical therapy.

10 PORTAL HYPERTENSION

Patrick S. Kamath, MD and David M. Nagorney, MD

Portal hypertension is diagnosed when the hepatic vein pressure gradient (HVPG), which reflects hepatic sinusoidal pressure, is more than 6 mm Hg. The elevation in portal pressure results in development of portosystemic venous collaterals, ascites, and hepatic encephalopathy. Each year, approximately 40,000 deaths within the United States are related to complications of cirrhosis, and the vast majority of these patients will die because of complications of either hepatocellular carcinoma or portal hypertension.

Pathogenesis of Portal Hypertension

As in all vascular systems, portal pressure is a product of portal blood flow and resistance to portal flow.¹ Portal hypertension may, therefore, result from increases in portal blood flow, increases in portal vascular resistance, or a combination of these factors.² The initiating event in portal hypertension secondary to cirrhosis is increased resistance to portal blood flow. The site of increased portal resistance depends on the etiology of portal hypertension. Although the site of increased portal resistance has been classified broadly as presinusoidal, sinusoidal, and postsinusoidal, this scheme oversimplifies the actual sites of resistance. In fact, multiple levels of resistance exist for various causes of cirrhosis.³ In alcoholic cirrhosis and cirrhosis secondary to viral hepatitis, the increase in resistance is at the level of hepatic sinusoids, whereas cirrhosis secondary to primary biliary cirrhosis has, in addition, a presinusoidal component. In schistosomiasis, which is arguably the most frequent cause of portal hypertension worldwide, the site of increased resistance is in the presinusoidal portal venules. In extrahepatic portal vein obstruction, the increased resistance is in the portal vein and its tributaries, whereas in Budd-Chiari syndrome, increased resistance is at the level of the hepatic venous outflow tract.⁴ In contrast to most patients who develop portal hypertension from chronic liver disease, the initial stage of portal hypertension in patients with an arteriovenous fistula is secondary to increases in portal blood flow. Increased portal blood flow, however, is an uncommon cause of portal hypertension.

In cirrhosis, increased resistance to vascular flow may be secondary to mechanical or vascular factors. Mechanical factors include fibrosis and nodularity, which distort the portal vasculature. Vascular factors that contribute to increased intrahepatic vasoconstriction include an elevation in the vasoconstrictor endothelin and a decrease in vasodilator substances such as nitric oxide.⁵ These vasoactive substances are potential targets for the development of drugs to decrease portal pressure. The increase in portal venous flow is secondary to splanchnic vasodilatation and an increase in the cardiac output.

Development of Collateral Circulation and Varices

The portosystemic collateral circulation develops in response to the elevation of portal pressure. Under normal circumstances, there is minimal perfusion of these collaterals and blood flow in these vessels is toward the liver. In portal hypertension, when portal pressure exceeds systemic venous pressure, flow is reversed in these collaterals, which then gradually expand. The sites of these collaterals are where the splanchnic circulation is closely apposed to the systemic circulation. Collaterals develop typically in the distal esophagus and proximal stomach; in the rectum, where the inferior mesenteric vein connects with the pudendal vein; around the umbilicus, where the vestigial umbilical vein communicates between the left portal vein and epigastric veins; and in the retroperitoneum in women, between the mesenteric and the ovarian veins.

The development of gastroesophageal varices requires a portal pressure gradient of at least 10 mm Hg as determined by the HVPG. Moreover, an HVPG of at least 12 mm Hg is required before variceal bleeding occurs. Variceal bleeding is related to variceal wall tension, which is directly proportionate to the transmural pressure gradient between the variceal lumen and the lumen of the esophagus, and the variceal radius and is inversely proportionate to variceal wall thickness. Varices are most likely to bleed at the lower end of the esophagus because at this site, the varices are of larger diameter and thin walled. The transmural pressure gradient is higher in the esophagus compared with the stomach because intrathoracic pressure is negative. Moreover, the varices lack tissue support in the lower end of the esophagus and are thin walled.

Diagnosis of Portal Hypertension

Portal hypertension is suspected clinically in a patient with stigmata of chronic liver disease such as jaundice, spider nevi, palmar erythema, Dupuytren contractures, gynecomastia, testicular atrophy, and splenomegaly. Caput medusae, which are dilated veins around the umbilicus, suggest an intrahepatic cause of portal hypertension. The presence of ascites with splenomegaly makes the presence of esophageal varices even more likely. A bruit may be heard in the left or right upper quadrant in patients with a splanchnic arteriovenous fistula as a cause of portal hypertension, whereas a venous hum in the epigastrium represents collateral flow in the falciform ligament. Alterations in mental status and asterixis, although rarely presenting findings, may be evident also.

Laboratory studies usually reveal evidence of hepatic dysfunction. Hypersplenism associated with cirrhosis is characterized by a mild to moderate thrombocytopenia and

leukopenia. Anemia may be present from recent hemorrhage, hemolysis, or malnutrition. Electrolyte abnormalities, including hyponatremia, hypokalemia, azotemia, and acid-base derangements, may also be present. As hepatic dysfunction progresses, coagulation factors synthesized by the liver are reduced, and, consequently, the prothrombin time and international normalized ratio increase. Similarly, a degree of hyperbilirubinemia occurs with either chronic or acute hepatic decompensation. Serum aminotransferases are elevated variably and partially reflect a degree of hepatocellular necrosis with the underlying liver process.

Determination of the Severity of Liver Disease

The two most commonly used methods to assess the severity of liver disease are the Child-Turcotte-Pugh (CTP) class and the Model for End-stage Liver Disease (MELD) score (<http://www.mayoclinic.org/meld/mayomodel5.html>). The components of the CTP class and the CTP score are shown in Table 1. The MELD score is currently used to prioritize allocation of organs for liver transplantation within the United States and many other countries. The advantages of the MELD score over the CTP score are that it uses only objective variables (the CTP score includes ascites and hepatic encephalopathy, which have a subjectivity in determination), has no ceiling or floor effects (e.g., in the CTP system, a serum bilirubin level of > 3 mg/dL and a bilirubin level of 30 mg are both given the same score, and albumin levels of 2.8 g/dL and 1.8 g/dL are also given the same score), and has extensive prospective validation. However, the CTP score is used more commonly in stratifying perioperative risk, especially as it relates to surgery for portal hypertension. Importantly, both the CTP class and MELD score are predictive of operative risk of death in patients with cirrhosis undergoing any major operation.⁶ However, only the MELD score is predictive of long-term survival.⁷

The most accurate method of diagnosing portal hypertension is measuring the HVP, which is the gradient between the wedged hepatic vein pressure (WHVP) and the free hepatic vein pressure (FHVP).⁸ Measurement of the HVP requires passage of a balloon catheter under fluoroscopic

guidance into the hepatic vein. Measurement of the pressure with the balloon inflated and occluding the hepatic vein represents the WHVP, and the pressure with the balloon deflated represents the FHVP. The HVP may be used to monitor portal pressure in patients on pharmacologic treatment, as a prognostic marker; to assess the risk of hepatic resection in patients with cirrhosis; and to determine the cause of portal hypertension, that is, presinusoidal, sinusoidal, or postsinusoidal.

In selected circumstances, direct pressure of the portal vein may be carried out through a percutaneous transhepatic route when HVP cannot be measured, as in patients with Budd-Chiari syndrome, in whom the hepatic veins are occluded, or in patients with an intrahepatic presinusoidal cause of portal hypertension where the HVP is normal.

Detection of Varices

Upper gastrointestinal endoscopy is the most common method used to detect varices. All patients with cirrhosis of the liver who are potential candidates for prophylactic treatment with either endoscopic variceal ligation or nonselective beta blockers should be screened for esophageal varices by upper endoscopy. Large varices are seen in about 15 to 20% of patients with cirrhosis screened by endoscopy. If no varices are detected at the initial endoscopy, then a repeat endoscopy should be carried out in 2 to 3 years. On the other hand, if only small esophageal varices are noted, then the procedure should be repeated in 1 to 2 years. Endoscopic grading of varices is subjective. The most acceptable classifications of varices at endoscopy are small (< 5 mm in diameter) and large (≥ 5 mm in diameter). In patients with large esophageal varices, Child-Pugh class C, and red-colored signs on varices, the risk of bleeding within 1 year is the highest.

Ultrasound examination has been used to confirm splenomegaly and detect thrombosis in the portal venous system. Fibroelastography, using either ultrasonography or magnetic resonance imaging, is a new technique to study liver stiffness⁹ and may be helpful in detecting portal hypertension but cannot be used to monitor changes in portal pressure. Multi-detector row computed tomography is an emerging modality for the detection of esophageal varices, as is capsule endoscopy.¹⁰ However, liver biopsy is still the gold standard for the diagnosis of cirrhosis,¹¹ and upper endoscopy is the standard for grading of varices.

Table 1 Child-Turcotte-Pugh Classification of Severity of Liver Disease

Parameter	Points Assigned		
	1	2	3
Ascites	Absent	Slight	Moderate
Bilirubin	< 2 mg/dL	2–3 mg/dL	> 3 mg/dL
Albumin	> 3.5 g/dL	2.8–3.5 g/dL	< 2.8 g/dL
Prothrombin time			
Seconds over control	< 4	4–6	> 6
INR	< 1.7	1.7–2.3	> 2.3
Encephalopathy	None	Grade 1–2	Grade 3–4

INR = international normalized ratio.

A total score of 5 to 6 is graded as class A (well-compensated disease), 7 to 9 is class B (significant functional compromise), and 10 to 15 is class C (decompensated disease).

Modalities for Treatment of Portal Hypertension-Related Bleeding

Treatment of portal hypertension is traditionally aimed at decreasing portal pressure by decreasing portal blood flow with pharmacologic agents or through the creation of porto-systemic shunts, using radiologic or surgical techniques as a means of decreasing resistance to portal blood flow. Treatment may also be focused directly on the varices using endoscopic techniques for ablation. Rarely, surgical devascularization is used in isolated segments of the gastrointestinal tract with varices to control bleeding when other alternatives have been exhausted. Currently, there are no pharmacologic agents that can decrease intrahepatic resistance to portal blood flow.

PHARMACOLOGIC THERAPY

The pharmacologic agents that decrease splanchnic blood flow are vasopressin and its analogues, somatostatin and its analogues, and nonselective beta-adrenergic blockers. Vasopressin and somatostatin and their analogues are given parenterally and are used only in the acute situation. Vasopressin, a splanchnic vasoconstrictor, can control acute bleeding in nearly half of patients but is not currently used because of an increased risk of cardiovascular ischemia. The semisynthetic analogue of vasopressin, terlipressin, has been used extensively in Europe because of its superior safety profile but is not currently available in the United States. The agent most commonly used within the United States is the somatostatin analogue octreotide because of its safety profile. Octreotide reduces portal pressure by decreasing portal blood flow through arteriolar splanchnic vasoconstriction. Octreotide is administered intravenously as a bolus of 50 mg followed by a continuous infusion at the rate of 50 µg/hr.

Nonselective beta-adrenergic agents are the preferred treatment for long-term use in decreasing portal pressure. A nonselective beta blocker is essential because blockade of beta₁-adrenergic receptors in the heart decreases cardiac output, whereas blockade of beta₂-adrenergic receptors results in decrease in portal blood flow. Of the two nonselective beta blockers, nadolol is preferred to propranolol because it is excreted predominantly by the kidney and has lower lipid solubility, which is associated with a lower risk of central nervous system side effects. The initial starting dose of nadolol is 20 mg daily and that of propranolol is 40 mg daily as a long-acting preparation. The dose of the agents is titrated upward every 3 to 5 days until a target heart rate of 55 to 60 beats per minute is reached or a decrease in resting heart rate by 25% is achieved. Nitrates act by causing venous dilatation and decreased portal blood flow because of the resulting reflex splanchnic vasoconstriction. Nitrates are seldom used within the United States because of the inability of most patients to tolerate the medication for prolonged periods because of headaches.

ENDOSCOPIC THERAPY

Endoscopic therapy is the only modality that can be used to prevent variceal bleeding, control variceal bleeding, and prevent variceal rebleeding. The preferred technique is endoscopic variceal ligation. Multiband devices are available that can apply several bands without withdrawal of the endoscope. The procedure involves suctioning of the varix into the device at the end of the endoscope. A band is then deployed around the varix, which strangulates the vessel and causes thrombosis. Banding the varices is started at the gastroesophageal junction and, moving more proximally in a spiral fashion, banding varices at approximately 2 cm intervals. Care should be taken to avoid applying the bands at the same level because of the risk of triggering esophageal strictures. Complications of variceal ligation include esophageal ulceration and esophageal strictures. Pulmonary aspiration may also occur.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNTS

A transjugular intrahepatic portosystemic shunt (TIPS) functions effectively as a side-to-side portocaval shunt [see Figure 1]. The technique involves creating a communication in the intrahepatic portion of the liver between the hepatic vein and a portal vein. Because TIPS functions like a side-to-side portocaval shunt, it may be used to treat not only acute or recurrent variceal bleeding but also refractory ascites, Budd-Chiari syndrome, and hepatic hydrothorax. The TIPS placement is usually performed with the patient under sedation. A platelet count of more than $60 \times 10^3/\mu\text{L}$ and an international normalized ratio less than 1.4 are usually recommended. The hepatic vein is cannulated through a transjugular approach by an interventional radiologist. Using a Rosch needle, the portal vein is cannulated through the intervening liver from the hepatic vein. The tract is dilated over a guidewire, and an expandable metal stent is placed across the tract to reduce the portocaval pressure gradient to below 12 mm Hg. The stent may be balloon dilated to reduce the pressure so that the target pressure of less than 12 mm Hg

Figure 1 Transjugular intrahepatic portosystemic shunt (TIPS). (a) Portogram demonstrating gastroesophageal varices and portal perfusion of the liver. (b) Portogram following creation of TIPS. Note the absence of portal hypertension.

is reached. A coated stent is preferred nowadays. The uncoated portion anchors the stent to the portal vein, whereas the polytetrafluoroethylene-coated portion lines the tract within the liver. Shunt stenosis is reduced when coated stents are used. TIPS can be placed successfully in over 95% of patients and is associated with a procedure-related mortality of approximately 1%.¹² Complications may occur early or late. Intra-abdominal bleeding is the most serious immediate complication. Long-term complications are related to shunt stenosis. Survival of patients following placement of a TIPS may be determined using the MELD score.¹³ Follow-up ultrasonography at 6-month intervals is recommended as surveillance for shunt patency. The patency of TIPS can usually be maintained through repeated radiographic intervention.

Surgery for Portal Hypertension

Surgical treatment for portal hypertension includes portosystemic shunts, nonshunt procedures, and liver transplantation. Nowadays, surgical procedures are used infrequently for patients with portal hypertension from cirrhosis because of the efficacy of orthotopic liver transplantation. In fact, all patients with variceal bleeding who meet minimal listing criteria for liver transplantation, that is, a CTP score of 7 or greater, should be evaluated for liver transplantation before any nontransplant surgical procedure is undertaken. Portal hypertensive bleeding should be managed preferably by nonoperative alternatives as a bridge to transplantation, and only failure of nonoperative management should prompt consideration of operative intervention. Patients who are CTP class A are the best candidates for nontransplant operations for portal hypertension from cirrhosis. However, patients with portal hypertension and variceal bleeding from portal vein thrombosis should be evaluated for nontransplant procedures. The choice of nontransplant procedure is dependent on the presence or absence of underlying liver disease, the patency of the portal venous system, the acuity of the variceal hemorrhage and its response to nonsurgical therapy, and candidacy for liver transplantation.

NONSHUNT SURGICAL PROCEDURES

Nonshunt procedures include esophageal transection and gastroesophageal devascularization. These procedures are generally reserved for patients whose underlying portal venous anatomy precludes portosystemic shunting.

Esophageal Transection

Esophageal transection involves division and reanastomosis of the esophagus, usually by stapling, to disrupt esophageal varices. Often splenectomy is performed to further reduce portal blood flow. The Sugira procedure has been the primary transection procedure employed and is usually coupled with selective vagotomy. Importantly, this operation attempts to maintain patency of paraesophageal collaterals to permit the development of additional portoazygous collaterals, thus diverting the hypertensive portal blood flow from the esophagogastric junction. This procedure has reportedly been safe and highly effective in controlling variceal bleeding and is associated with a lower risk of encephalopathy than that for portosystemic shunts in the East but not in the West. Patient

selection and modifications in the originally described technique likely account for the differences in outcome. Esophageal transection typically has been undertaken when patients continued to bleed from esophageal varices despite two endoscopic sessions within a 24-hour period. With the increasing use of emergency TIPS to control acute variceal bleeding, esophageal transection is seldom used.

Devascularization Procedures

Devascularization procedures are performed to prevent recurrent variceal bleeding in patients with CTP class A in whom a portosystemic shunt is precluded, either surgically or radiologically. Typically, these procedures are employed in patients with extensive splenic and portal venous thrombosis. As originally described by Sugira, combined thoracotomy and laparotomy approach was required, but, subsequently, the operation has been carried out through an abdominal approach combined with a splenectomy.¹⁴ Total devascularization of the greater curvature of the stomach and the upper two thirds of the lesser curvature of the stomach and circumferential devascularization of the lower 7.5 cm of the esophagus are required [see Figure 2]. The rate of recurrent bleeding following this procedure depends a great deal on the extent of devascularization and may be as high as 40% if devascularization is incomplete.

PORTOSYSTEMIC SHUNTS

Surgical portosystemic shunts are divided into selective shunts, partial shunts, and total portosystemic shunts.

Selective Shunts

Selective shunts isolate and decompress only a portion of the portal venous system, that is, only the gastroesophageal junction, proximal stomach, and spleen. The most widely used selective shunt is the distal splenorenal shunt or Warren shunt [see Figure 3]. Portal hypertensive blood flow is maintained to the liver through the uninterrupted superior mesenteric and portal veins; therefore, selective shunts are ineffective in treating ascites. The distal splenorenal shunt is constructed by anastomosing the distal end of the splenic vein from the preserved spleen to the side of the left renal vein. The right and left gastric and right epiploic veins and greater curve perforating branches to the gastroepiploic vein are ligated, but the short gastric veins are preserved to decompress the gastroesophageal junction through the shunt. Additionally, all pancreatic branches to the splenic vein from the splenic hilus to the portal vein are divided to prevent the late loss of selectivity of this shunt. In expert hands, the distal splenorenal shunt can prevent variceal bleeding in more than 90% of patients with low operative mortality and morbidity and a low risk of hepatic encephalopathy.

Partial Portosystemic Shunts

A partial portosystemic shunt is actually a type of side-to-side portocaval shunt, but the shunt is calibrated by the size of the synthetic interposition graft placed between the portal vein and the inferior vena cava. Shunt diameters of 8 mm usually reduce the portal pressure to less than 12 mm Hg and maintain most antegrade portal blood flow to the liver. Construction of a partial shunt is technically simpler than

Figure 2 By extensively devascularizing the esophagogastric junction, this procedure may provide a means of interrupting esophagogastric varices without portosystemic shunting.

construction of a distal splenorenal shunt. Although partial shunts are nonselective because they do not selectively decompress an isolated portion of the portal system, their efficacy in terms of reduction of variceal bleeding and the rate of encephalopathy are similar to that seen with a distal splenorenal shunt.

Nonselective Portosystemic Shunts

Nonselective shunts effectively decompress the entire portal venous system and divert portal blood flow from the liver to a significant degree. Nonselective portosystemic shunts include the end-to-side and side-to-side portocaval shunts, the central splenorenal shunt [see Figure 4a]), and the meso-caval shunt [see Figure 4b)]. The end-to-side portocaval shunt [see Figure 4c)], which was an excellent procedure for preventing variceal bleeding but which could not be used to treat ascites because hepatic sinusoidal pressure was maintained, is no longer used. Nowadays, the side-to-side portocaval shunt is used predominantly [see Figure 4d)]. Any portocaval shunt more than 12 mm in diameter results in almost total shunting of portal blood flow. These shunts are very effective in

controlling bleeding and ascites because the hepatic sinusoids are decompressed, but hepatic encephalopathy occurs in about 40% of patients followed long term. Moreover, these shunts may be associated with increased morbidity and intra-operative transfusion requirements in those patients who undergo liver transplantation.

Management of Specific Causes of Portal Hypertension–Related Bleeding

ESOPHAGEAL VARICES

Large esophageal varices are seen in approximately 20% of patients with cirrhosis screened by upper endoscopy. In patients who do not have esophageal varices at the initial endoscopy, the annual rate of development of new varices is approximately 5%. In patients in whom small varices are noted at initial endoscopy, progression to large varices occurs at a rate of about 10% per year. The rate of progression in variceal size is related to increases in portal pressure related to changes in liver fibrosis in liver function. On the other

Figure 3 The distal splenorenal shunt (DSRS) diverts portal flow from the spleen and short gastric veins into the left renal vein. The DSRS provides selective shunting by preserving portal flow from the mesenteric circulation. Potential sites of collateralization (e.g., the left gastric vein, the gastroepiploic vein, and the umbilical vein) are routinely interrupted to preserve hepatopedal portal flow.

hand, improvement in liver function in patients with alcoholic liver disease may be associated with a decrease in or even disappearance of varices. Without prophylactic treatment, the risk of bleeding in patients with small varices is 7% at 2 years, whereas the risk of bleeding in patients with large varices is 30% at 2 years. Bleeding is virtually absent when the HVPG is below 12 mm Hg. In patients who bleed, the risk of death with acute variceal bleeding is 5 to 8% at 1 week and about 20% at 6 weeks. Patients with a higher MELD score and those who require greater than 4 units of packed red blood cell transfusions are at the highest risk of death.¹⁵

Treatment of esophageal variceal bleeding is classified as either (a) primary prophylaxis to prevent the first bleeding [see Figure 5]; (b) control of acute variceal bleeding [see Figure 6]; or (c) secondary prophylaxis to prevent rebleeding in patients in whom the initial bleeding is controlled [see Figure 7].¹⁶

Primary Prophylaxis

Either nonselective beta blockers or endoscopic variceal ligation should be considered in patients with large varices.

In patients with CTP class C cirrhosis, small varices should also be considered for treatment with a beta blocker. The benefit of primary prophylaxis is greatest in patients with large varices, with the prevention of variceal bleeding in approximately one of 10 patients treated. Either nadolol or a long-acting preparation of propranolol may be used. In approximately 15% of patients, the drug is discontinued because of side effects. The physiologic goal of treatment with beta blockers is a resting heart rate of between 55 and 60 beats per minute, provided that the systolic blood pressure is more than 90 mm Hg. If patients are started on pharmacologic treatment, follow-up endoscopy is not required unless gastrointestinal bleeding occurs.

Endoscopic variceal ligation is an alternative treatment. Variceal ligation is associated with a lower risk of bleeding and bleeding-related mortality than therapy with beta blockers, but overall mortality is similar. Complications of variceal ligation include esophageal ulcers and strictures, which may be severe but are infrequent with careful technique. Beta blockers are cheaper and convenient to use and may also reduce the

Figure 4 Nonselective portosystemic shunts either immediately or eventually divert all portal blood flow from the liver into the systemic venous circulation. Shown are the four main variants: (a) conventional (proximal) splenorenal shunt, (b) interposition shunt (portacaval [1], mesocaval [2], and mesorenal [3]), (c) end-to-side portacaval shunt, and (d) side-to-side portacaval shunt.

risk of bleeding from gastric varices and portal hypertensive gastropathy, but the side effects are more frequent. Therefore, the choice of therapy should be individualized.

Control of Acute Esophageal Variceal Bleeding

The aims of treatment in a patient with active esophageal variceal bleeding are resuscitation of the patient, control of hemorrhage, and prevention of complications such as infections and liver-specific conditions such as ascites and hepatic encephalopathy. Two large-caliber intravenous access catheters should be inserted as the patient is evaluated. Red blood cells are transfused with the goal of maintaining the hematocrit around 25% and coagulopathy is corrected as indicated.

Endotracheal intubation is advisable in the presence of active bleeding. Antibiotics should be administered to all patients to prevent bacteremia. Norfloxacin 400 mg orally twice daily, intravenous ciprofloxacin 400 mg every 12 hours, ceftriaxone 1 g every 24 hours, or levofloxacin 500 mg every 24 hours for 7 days is recommended. Pharmacologic therapy with vasoactive agents should be started as early as possible. Within the United States, the vasoactive agent most commonly used is octreotide. Endoscopic treatment is undertaken as soon as the patient is hemodynamically stable and the vasoactive agent has been infused for at least 30 minutes. Esophageal variceal bleeding is confirmed if active bleeding is seen from the varices or a white fibrin plug or red blood clot is noted

Figure 5 Esophageal variceal bleeding: primary prophylaxis. EGD = esophagogastroduodenoscopy.

Figure 7 Esophageal variceal bleeding: secondary prophylaxis.
TIPS = transjugular intrahepatic portosystemic shunt.

over a varix. Esophageal varices are considered the site of bleeding if blood is seen in the stomach and no other bleeding source is identified.

Acute variceal bleeding cannot be controlled by endoscopic variceal ligation and pharmacotherapy in approximately 10% of patients. When two endoscopic sessions within a 24-hour period fail to control variceal bleeding, TIPS should be considered. Balloon tamponade with either a Minnesota tube or a Sengstaken-Blakemore tube may be used to control bleeding until TIPS is undertaken. Emergency surgical shunts have largely been abandoned.

Secondary Prophylaxis

All patients who have had even a single episode of esophageal variceal bleeding should receive prophylactic therapy to reduce the risk of recurrent bleeding from esophageal varices. In the absence of prophylactic therapy (secondary prophylaxis), nearly 80% of these patients will have recurrent variceal bleeding at 2 years. Pharmacologic therapy with nonselective beta blockers, endoscopic therapy, and portosystemic shunts (both surgical and TIPS) either alone or in combination have been used for secondary prophylaxis.¹⁷

The preferred initial treatment to prevent variceal rebleeding is a combination of endoscopic variceal ligation and a nonselective beta blocker. Isosorbide mononitrate is seldom used in the United States as patients typically are intolerant of this medication after beta blockade. Endoscopic variceal ligation alone is carried out in patients who are intolerant of beta blockers. Following control of the acute variceal bleeding with variceal ligation, the next session of endoscopic variceal ligation is carried out at 7 to 14 days. Subsequent sessions are repeated every 3 to 4 weeks until esophageal varices are ablated. If patients have recurrent bleeding after endoscopic variceal ligation alone, beta blockers are added. Conversely, if patients are initially started on nonselective beta blockers alone and have recurrent bleeding, endoscopic

variceal ligation is added. For those patients with recurrent bleeding after a combination of endoscopic variceal ligation and beta blocker therapy, an evaluation for a portosystemic shunt is recommended. TIPS is the preferred modality in patients with Child-Pugh class B and C cirrhosis. Even in patients with Child-Pugh class A cirrhosis, the TIPS procedure may be as effective as a distal splenorenal shunt,¹⁸ but the choice of therapy depends on local expertise.

GASTRIC VARICES

The two classes of gastric varices are gastroesophageal varices (GOVs) and isolated gastric varices (IGVs). Gastric varices are classified as type 1 gastroesophageal varices (GOV1), which extend below the gastroesophageal junction and are in continuity with esophageal varices, and type 2 gastroesophageal varices (GOV2), which extend into the cardia and fundus of the stomach but are in continuity with the esophageal varices. Varices in the fundus of the stomach in the absence of esophageal varices are called isolated gastric varices. GOV1 varices comprise approximately 70% of all gastric varices. Type 1 isolated gastric varices (IGV1) are in the fundus, whereas varices that occur elsewhere in the stomach in the absence of esophageal varices are termed IGV2. Although splenic vein thrombosis usually causes IGV1, the most common cause of fundic varices overall is probably cirrhosis. Gastric varices occur in association with advanced portal hypertension, and bleeding is more common in patients with GOV2 and IGV1. Gastric varices that bleed tend to be larger than esophageal varices and are likely to bleed only when their diameter is greater than 1 cm.

Primary Prophylaxis

No studies have evaluated pharmacologic or endoscopic treatment for primary prophylaxis of gastric variceal hemorrhage. In patients with CTP class C with large gastric varices,

pharmacologic treatment with nonselective beta blockers may be started to prevent variceal bleeding. Endoscopic therapy is not currently recommended as primary prophylaxis for gastric variceal bleeding.

Control of Bleeding

The principles of treatment for patients with gastrointestinal bleeding from gastric varices again include volume resuscitation, antibiotic prophylaxis, and a vasoactive agent such as octreotide [see Figure 8].¹⁹ Endoscopic treatment is performed only after endotracheal intubation because these patients typically have large-volume bleeding. A diagnosis of gastric variceal hemorrhage is sometimes difficult because blood pools in the fundus of the stomach. Gastric variceal hemorrhage is suspected whenever bleeding is noted from a gastric varix; if blood is found in the stomach and gastric varices with a white nipple sign are noted; if active bleeding is seen at either the gastroesophageal junction or in the gastric fundus; or if blood is seen in the stomach and gastric varices are noted in the absence of other lesions in the esophagus and stomach.

The preferred endoscopic treatment for fundal gastric variceal bleeding is injection of cyanoacrylate polymers, usually N-butyl-2-cyanoacrylate in the United States.²⁰ These cyanoacrylate tissue adhesives are not licensed for use in the United States for variceal injection. Varices are obliterated when the cyanoacrylate adhesives harden on contact with blood. Cyanoacrylate glue injection is superior to both endoscopic variceal ligation and alcohol sclerotherapy in the treatment of gastric fundal varices. Pulmonary and cerebral emboli have been reported, especially in patients with spontaneous large portosystemic shunts or intrapulmonary shunts, and may even be associated with mortality.

If endoscopic and pharmacologic therapies have failed to control gastric variceal hemorrhage, TIPS is performed. A Linton-Nachlas tube with a 600 mL volume gastric balloon may be used temporarily to tamponade bleeding from gastric varices in patients requiring TIPS. The Minnesota tube and the Sengstaken-Blakemore tube with only 250 mL gastric balloons are not as effective.

Secondary Prophylaxis

No control trials have determined the preferred therapy for the prevention of recurrent gastric variceal bleeding. Cyanoacrylate glue injection for secondary prophylaxis has been used with excellent results. Alternatively, transvenous obliteration of gastric varices can also be undertaken in patients with demonstrable spontaneous splenorenal shunts. This technique requires considerable radiologic skill and is currently popular only in some centers in the Far East. TIPS is effective in preventing gastric variceal rebleeding in patients with cirrhosis. However, TIPS does not always result in a decrease in the size of gastric varices; therefore, the target HVPG in these patients is not clear.

ECTOPIC VARICES

Varices that occur at a site other than the gastroesophageal junction and stomach are termed ectopic varices.²¹ Ectopic varices account for fewer than 5% of all variceal-related bleeding. Depending on the site of rupture of the varices, clinical manifestations include melena, hematemesis, hemobilia, hematuria, and retroperitoneal or intraperitoneal bleeding. Ectopic varices occur in patients with both extrahepatic portal vein obstruction and cirrhosis.

The most common site of ectopic varices is the duodenum. The site of gastrointestinal stomas, particularly in patients with

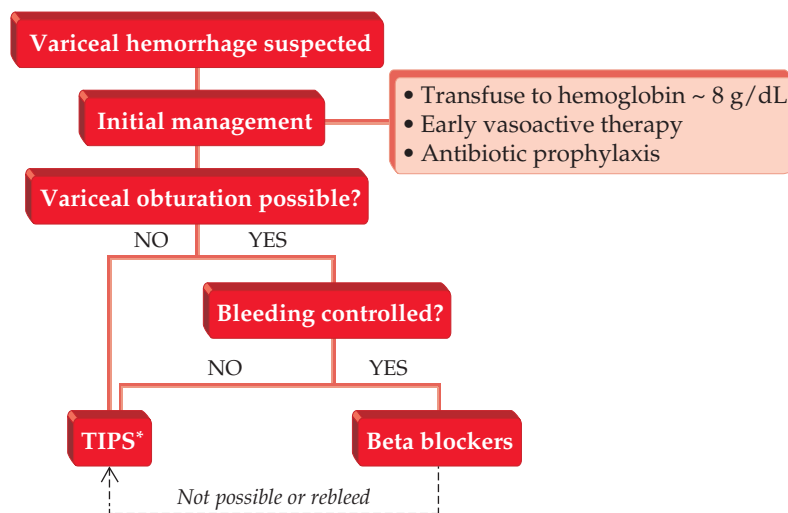

Figure 8 In patients with acute gastric variceal bleeding, initial management consists of transfusion to a hemoglobin of 8 g/dL, pharmacotherapy with vasoactive agents, and antibiotic prophylaxis. Endoscopic treatment is carried out, but if acute hemorrhage is not controlled, transjugular intrahepatic portosystemic shunt (TIPS) is recommended. If the acute hemorrhage is controlled and cyanoacrylate is available, obliteration of the gastric varices is attempted with cyanoacrylate. If cyanoacrylate is not available, then TIPS is recommended.

*A surgical shunt may be considered in patients with Child-Turcotte-Pugh class A cirrhosis.

inflammatory bowel disease and primary sclerosing cholangitis who have had an ileostomy following proctocolectomy, is the next most frequent. Peristomal varices present as a bluish halo surrounding the stoma. Anorectal varices are noted in about 10 to 40% of patients with cirrhosis who undergo colonoscopy.

In patients with suspected ectopic variceal bleeding, vasoactive drugs may be used initially. If the ectopic varices are visualized endoscopically, as in the duodenum or colon, they are treated with band ligation or glue injection. Colonic varices may require application of hemostatic clips. Stomal varices are initially treated with local compression, but, subsequently, patients require either transhepatic embolization of the stomal varices or TIPS.

Ectopic varices that present as intraperitoneal hemorrhage are associated with a poor outcome because the diagnosis is often made late and patients may require a laparotomy.

PORTAL HYPERTENSIVE GASTROPATHY AND GASTRIC VASCULAR ECTASIA

Portal hypertensive gastropathy is common in patients with cirrhosis and is characterized by a cobblestone appearance of the gastric mucosa on endoscopy. If red spots are superimposed on the cobblestone appearance, the patients are said to have severe portal hypertensive gastropathy. Gastric vascular ectasia is an entity in which there are ectatic vessels in the absence of a background mosaic pattern. When these vascular aggregates occur in the antrum of the stomach arranged in a linear pattern, the term *watermelon stomach* is used. If the aggregates are more widely dispersed, the term used is *gastric antral vascular ectasia*. Portal hypertensive gastropathy responds to beta blockers or TIPS. However, vascular ectasia may require thermoablative therapy and, occasionally, antrectomy. TIPS does not reduce the risk of bleeding from gastric vascular ectasia.²²

ASCITES

The initiating event in the formation of ascites is sinusoidal portal hypertension. The resulting splanchnic vasodilatation results in a decrease in the effective arterial blood volume. As a means of increasing the circulating intravascular volume, there is activation of the renin-angiotensin-aldosterone system, vasopressin, and the sympathetic nervous system. The net result of these actions is renal retention of sodium and water and renal vasoconstriction. The excess fluid is compartmentalized into the peritoneal space because of portal hypertension. Spontaneous bacterial peritonitis (SBP) is caused by infection of ascites in the absence of a perforated viscus. As cirrhosis progresses, there is further splanchnic vasodilatation and renal vasoconstriction. Ultimately, refractory ascites and hyponatremia, both of which are associated with decreased survival, occur. When renal vasoconstriction occurs and the serum creatinine is greater than 2.5 mg/dL, the condition is termed type 1 hepatorenal syndrome, which is associated with a median survival of only 2 weeks without treatment. When the serum creatinine rises above 1.5 mg/dL, patients are said to have type 2 hepatorenal syndrome, the major manifestation of which is refractory ascites. The median survival in patients with refractory ascites is 6 months. Another manifestation associated with increased renal retention of sodium and water is hepatic hydrothorax, that is, pleural effusions in the presence of ascites.

Treatment of ascites is aimed toward maintaining a negative sodium balance.²³ Specifically, renal sodium losses should exceed sodium intake because extrarenal losses of sodium via perspiration and stooling are more limited and difficult to control. Patients with ascites are typically placed on a 2 g sodium restricted diet (88 mEq of sodium). Spironolactone is the preferred diuretic because it is an aldosterone antagonist. The maximum dose of spironolactone is 400 mg per day. Spironolactone alone can achieve adequate renal sodium losses in 60 to 70% of patients. Furosemide is added in escalating doses if sodium restriction and spironolactone alone do not result in a daily weight loss of more than 500 g per day. The goal of treatment with diuretics is to achieve a daily weight loss of 500 g per day in the absence of lower limb edema and 1 kg a day in the presence of edema. The dose of diuretics is increased every 3 to 5 days if weight loss is less than 200 g per day.

If, in spite of sodium restriction and diuretics, a weight loss of more than 200 g per day is not achieved, the patient has refractory ascites. Most of these patients have diuretic-intractable ascites; that is, ascites persists because further increases in the dose of diuretics are associated with complications such as hyponatremia, renal insufficiency, and hepatic encephalopathy. Patients in whom ascites cannot be adequately immobilized in spite of 400 mg of spironolactone and 160 mg of furosemide per day have diuretic resistance ascites.

When ascites is refractory to diuretic treatment, large-volume paracentesis is recommended. Albumin is infused in a dose of 6 to 8 g per liter of ascitic fluid removed to prevent renal dysfunction and rapid reaccumulation of ascites. If more than two to three large-volume paracenteses are required every month in spite of optimal sodium restriction and maximal diuretics, TIPS is performed. TIPS results in better control of ascites in more than 80% of patients, but it is associated with an increased risk of hepatic encephalopathy and no change in overall survival. A peritoneovenous shunt should be considered in patients with refractory ascites in whom venous anatomy precludes TIPS. Peritoneovenous shunts are avoided in patients who are candidates for liver transplantation because of the risk of procedure-related mortality and, potentially, peritoneal fibrosis around the catheter. Peritoneovenous shunts are associated with frequent shunt occlusion and disseminated intravascular coagulation. The Denver shunt is the only peritoneovenous shunt currently on the market.

SBP is suspected clinically in patients with ascites who develop fever and, sometimes, abdominal tenderness with associated hepatic and renal deterioration without an obvious abdominal source of infection. The diagnosis of SBP is confirmed by an absolute neutrophil count over 250/ μ L and a positive bacterial culture of the ascites. Unlike secondary bacterial peritonitis, SBP is typically monomicrobial and associated with low ascitic fluid total protein, most often less than 1 g/dL. Treatment for SBP is initiated promptly because the mortality risk approaches 25%. SBP is treated with intravenous cefotaxime 2 g every 8 hours for 5 days and infusion of albumin 1.5 g/kg on day 1 of treatment and 1 g/kg on day 3 of treatment. A repeat paracentesis is carried out in 48 hours to confirm a decrease in the absolute neutrophil count. If the absolute neutrophil count has not decreased by 25%, peritonitis secondary to a perforated viscus or diverticulitis should be suspected. Secondary bacterial peritonitis is also suspected

if the cultures are polymicrobial, anaerobic, or fungal. Computed tomography of the abdomen with oral contrast may be required for diagnosis in such patients. Following the resolution of SBP, norfloxacin 400 mg once daily is given indefinitely to prevent recurrence. Fluoroquinolones may also be used to prevent SBP in patients with low-protein ascites who have not previously had SBP.²⁴

HEPATIC ENCEPHALOPATHY

The neuropsychiatric manifestations of portal hypertension are termed hepatic encephalopathy. Hepatic encephalopathy requires a combination of portosystemic shunting and altered liver function. When hepatic encephalopathy occurs in the absence of significant hepatic dysfunction (MELD score < 15), a large portosystemic shunt should be suspected.

Precipitating factors for hepatic encephalopathy include gastrointestinal bleeding, infection, hypokalemia, dehydration, and excessive intake of animal proteins. Ammonia has been implicated in the pathogenesis of hepatic encephal-

opathy, but there is a poor correlation between circulating levels of ammonia and the severity of hepatic encephalopathy.

Hepatic encephalopathy is treated initially with oral lactulose given in a dose to produce two to three semiformal stools per day. Antibiotics such as neomycin, metronidazole, or rifaximin may be used in those patients who are intolerant of lactulose or in whom encephalopathy cannot be controlled in spite of optimal lactulose dosing. Dietary protein restriction is no longer recommended, but some patients may benefit from conversion to a predominantly vegetable protein diet. When a large portosystemic shunt can be demonstrated and liver dysfunction is not advanced (MELD < 15), occlusion of the portosystemic shunt can be carried out either radiologically or surgically.

11 CROHN DISEASE

Susan Galandiuk, MD, FACS, FASCRS

The role of surgery in the management of Crohn disease has undergone a dramatic evolution over the past 50 years. Currently, surgical treatment of Crohn disease is seldom performed in the emergency setting; it is nearly always performed after failed medical therapy. The decision to proceed with operative management is based on careful patient evaluation, with full awareness of the potential complications and ramifications of treatment. In particular, attention must be paid to the risk of recurrent disease, the possible surgical complications and knowledge of the side effects of medical therapy.

Classification

There are many systems for classifying Crohn disease. One of the simplest is the classification developed by Farmer and colleagues, which categorizes the disease on the basis of disease location alone (ileocolic, purely colonic, small bowel, and perianal).¹ A more elaborate system is the Vienna classification, which categorizes the disease on the basis not only of location but also of age at onset and disease behavior.² In this system, there are four categories for disease location: terminal ileum (L1), colon (L2), terminal ileum and colon (L3), and any location proximal to the terminal ileum (L4). There are two categories for age at onset: less than 40 years of age (A1) and 40 years of age or older (A2). Finally, there are three categories for disease behavior: nonstricturing and nonpenetrating (B1), stricturing (B2), and penetrating (B3).

Given that there are as many types and combinations of Crohn disease as there are patients with this condition, the most sensible approach is probably to use some combination of these two classification schemes. Careful evaluation of the specifics of each case will yield the best treatment results; however, general classification of the disease can help guide therapy. Broadly speaking, Crohn disease of the small bowel has the highest recurrence rate. Because of the important function of the small bowel in digestion, surgeons tend to emphasize conserving small bowel length during operative treatment of Crohn disease. Currently, however, there is an increasing focus on colon conservation with the aims of maintaining water absorption in patients and delaying (or perhaps eliminating) the need for a stoma.

Roles of Medical Therapy and Surgical Therapy

In planning treatment of Crohn disease, it is important not to make the use of medical therapy or surgical therapy an either/or issue. Just as one tool cannot be expected to fill every household need, operative management cannot be expected to solve every problem related to Crohn disease. Overall, careful use of medical therapy, appropriately combined with surgical therapy, provides the best treatment of Crohn disease. Single-minded reliance on either therapy to

the exclusion of the other often leads to inadequate patient care.

Generally speaking, except in the case of a free perforation, cancer, or dysplasia, one should not operate on a patient with Crohn disease without first attempting medical therapy. With the dramatically improved medical treatment options currently available, surgery can be avoided in many cases. This is often a desirable result, given the known risk of disease recurrence after surgical treatment of Crohn disease and the significant associated operative morbidity. In one single-center study, the reoperation rate for Crohn disease was 34% at 10 years.³ The agents used to treat Crohn disease can be divided into several broad groups: probiotics, antibiotics, antiinflammatory drugs, immunosuppressive drugs, and biologic agents. These can be used alone or in combination to treat disease and to maintain remission [see Table 1].

Few good studies have been done on the cost-effectiveness of medical or surgical therapy^{4,5} versus that of timely surgery followed by maintenance medical therapy. There is clearly a need for such studies. The use of potent and expensive immunomodulator therapy (e.g., maintenance infliximab) for simple ileocolic disease is questionable, especially in the light of studies indicating that such treatment is not at all

Table 1 Medical Treatment of Crohn Disease

innocuous.^{6,7} It is essential for the surgeon to be knowledgeable regarding the patient's medical therapy, particularly as there have recently been multiple reports of increased post-operative complications in patients receiving biologics prior to surgery.⁸⁻¹⁰

CHANGING CONCEPTS IN SURGERY FOR CROHN DISEASE

Although first described in the beginning of the 19th century, Crohn disease was not recognized as a discrete clinical entity until the first part of the 20th century.¹¹ At one point, it was treated surgically in much the same way as cancer, with frozen-section margins obtained at the time of resection. This approach did not yield any substantial reduction in the recurrence rate.¹² In fact, overzealous resections often resulted in Crohn patients' requiring lifelong parenteral nutritional support.¹³ Accordingly, conservative surgery is now the rule: only gross macroscopic disease is resected into palpably normal margins (in particular, a palpably normal mesenteric border of the bowel).

General Indications for Surgical Treatment

SIDE EFFECTS OF MEDICAL THERAPY

Significant side effects of medical therapy include those associated with failure to wean from prednisone (e.g., cataract formation, aseptic necrosis of the femoral head, and weight gain). Side effects of antimetabolite therapy include pancreatitis, neutropenia, and opportunistic infections. Side effects of biologic therapy can include reactivation of tuberculosis or histoplasmosis¹⁴ and, as with antimetabolite therapy, an increased risk of non-Hodgkin lymphoma.

COMPLICATIONS OF DISEASE

Lack of Response to Medical Therapy

Many patients with so-called toxic colitis do not respond satisfactorily to medical treatment. In severe cases of refractory disease, if surgery is not performed, colonic perforation, peritonitis, and multiple organ failure may ensue. Such cases are much less frequent now than they once were.

Obstruction

In many patients with Crohn disease, the behavior of the disease changes over time, from a more inflammatory and edematous process to one characterized more by fibrosis and scarring. Whereas antiinflammatory drugs are ideal for treating the former, surgery is frequently necessary for the latter. Failure to refer for surgical treatment of obstruction is, unfortunately, a common error among gastroenterologists. Severe abdominal pain is always a warning sign of obstruction and should be taken seriously. The importance of this point is illustrated by a case from my experience involving a patient who had obstructing ileocolic Crohn disease with gross proximal distention of the terminal ileum [see Figure 1]). This patient lost 20 lb, was experiencing severe abdominal pain, and was treated for more than a year with 6-mercaptopurine before being referred for operative management. Ileocolic resection led to rapid resolution of the symptoms.

Symptomatic Fistulas

Enterointestinal fistulas, by themselves, are no longer considered an absolute indication for operation in the absence of

Figure 1 Shown is an example of stenotic ileocolic Crohn disease resulting in obstructive symptoms that were not relieved by medical therapy.

Figure 2 Shown is an enterocutaneous fistula that persisted for more than 1 year after an ileocolic resection. The choice of parallel incisions by the previous surgeon made selection of a temporary stoma site much more difficult.

other complicating factors. Symptomatic fistulas, such as those associated with obstruction or those associated with disabling symptoms (e.g., rectovaginal fistulas or enterocutaneous fistulas [see Figure 2]), may have to be treated surgically. Ileosigmoid fistulas, which effectively bypass the entire colon, may be associated with profound and refractory diarrhea (i.e., > 20 bowel movements/day) and may also have to be treated operatively.

Abscess Formation

Abscesses are particularly common with ileocolic Crohn disease. If they cannot be controlled by means of computed tomography (CT)-guided drainage, surgical therapy may be indicated.

Cancer or Dysplasia

The risk of colorectal cancer is approximately three times higher in patients with Crohn disease than in the general population.¹⁵⁻¹⁷ Screening recommendations for patient's with long-standing Crohn colitis are similar to those for ulcerative colitis.¹⁸ In Crohn disease, cancer may also arise in long-standing fistula tracts.

Failure to Grow

In children, failure to grow and develop normally is one of the main indications that medical therapy for Crohn disease has been unsuccessful. Timely surgical therapy will permit normal development. On occasion, when bone age lags significantly behind chronological age, treatment with recombinant human growth hormone is required.

Special Considerations

PREGNANCY

Persons who have Crohn disease may be less fertile than healthy age-matched persons. One possible explanation for this difference is that feeling ill may result in reduced sexual desire or decreased sexual activity. Another is that pelvic inflammation caused by Crohn disease or by scarring and adhesion formation resulting from surgery may impair fertility. To reduce the chances of the latter, hyaluronic acid sheets may be placed around the tubes and ovaries; alternatively, the ovaries may be tacked to the undersurface of the anterior abdominal wall with absorbable sutures and thereby prevented from entering the pelvis and being trapped in scar tissue.

There is no evidence that pregnancy exacerbates Crohn disease; however, there are some specific concerns that apply to pregnant patients with this condition. Because patients with Crohn disease often have bowel movements that are more liquid, they have a particular need for a well-functioning anal sphincter. If there is any chance of an obstetrics-related injury (e.g., from a large baby in a primagravida or from a breech presentation), a cesarean section is advisable to minimize the risk of sphincter trauma. The same is true in the presence of severe perianal Crohn disease. During pregnancy, prednisone and 5-aminosalicylic acid (5-ASA) medications are safe, whereas drugs such as metronidazole are not.¹⁹ If imaging studies are needed, magnetic resonance imaging and ultrasonography are the modalities of choice.

MARKING OF STOMA SITES AND CHOICE OF INCISION

When a patient with Crohn disease is expected to need an ileostomy, it is extremely important to mark the site preoperatively. What looks flat when the patient is on the operating table may not be flat when he or she is upright. The patient must be asked to sit and lean over to confirm that the marked stoma site is in an area without folds, creases, or previous incisions. Stoma appliances do not adhere well to areas of previous scarring, and these should be avoided whenever possible.

Patients with Crohn disease do not react to intra-abdominal infection in a typical fashion. It is not unusual to find unsuspected abscesses that were not revealed by preoperative CT scans and other imaging studies. If there is even a remote chance of an unsuspected abscess (particularly in cases of obstructing ileocolic Crohn disease), the possibility of a temporary stoma should be raised with the patient and the proposed stoma site marked preoperatively.

A key point is the necessity of planning for the future. Many patients with Crohn disease will eventually require a stoma. Operating through a midline abdominal incision preserves all four quadrants for possible future stoma sites (if needed). Similarly, when surgery is performed laparoscopically, specimen retrieval sites should be kept away from potential stoma sites.

LAPAROSCOPY

Laparoscopic surgical techniques have gained acceptance in the treatment of Crohn disease. In performing a laparoscopic operation for Crohn disease, it is essential to adhere to the same technical standards that apply to corresponding open procedures. Careful intraoperative exploration of the abdomen is important in that many patients have multifocal disease. Without such exploration, patients may experience persistent postoperative symptoms as a consequence of persistent proximal pathologic states that were not addressed. As with other treatment modalities, there are some circumstances in which laparoscopy is particularly useful and others in which it should not be used. For example, a laparoscopic approach may not be suitable for fixed mesenteric abscesses associated with complex fistulae.

Ileocolic resection for Crohn disease also lends itself particularly well to a laparoscopically assisted approach; compared with open resection, laparoscopic resection has been reported to result in shorter hospital stays and reduced costs.^{20,21} The ileocolic vessels originate centrally, and they lie only over the retroperitoneum. Once the lateral peritoneal attachments are divided, the colon and the small bowel mesentery can be exteriorized, and the mesentery can be divided and the anastomosis performed extracorporeally.

Many studies have shown that even fistulizing Crohn disease can be safely addressed laparoscopically, depending on the skill of the surgeon. A hand-assisted approach is often useful with cases of dense fixation, in which fistulas are common and finger dissection may facilitate definition of the anatomy. If in doubt, one should not hesitate to convert to an open procedure. Typically, most areas that feel fibrotic or contain fibrotic adhesions are actually areas of fistulizing disease and should be treated as such until proved otherwise. In one study, patients with recurrent disease, those older than 40 years, and those with an abdominal mass were more likely to require conversion to an open procedure.²²

Surgical Management of Crohn Disease at Specific Sites

ESOPHAGEAL, GASTRIC, AND DUODENAL DISEASE

Crohn disease of the upper alimentary tract can be difficult to diagnose, largely because it is relatively uncommon. Obstructing strictures as a result of Crohn disease in this area are unusual; the unsuspected finding of noncaseating granulomas in biopsies of erythematous areas in a patient with Crohn disease in other locations is diagnostic.

Occasionally, a patient with Crohn disease of the distal esophagus requires dilatations, but this is uncommon. Surgical treatment for Crohn disease of the upper alimentary tract is almost exclusively reserved for disease affecting the duodenum. Diagnosis of duodenal Crohn disease can be difficult and requires a certain amount of suspicion. Frequently, the diagnosis is not made until relatively late because diagnostic imaging tends to focus on endoscopy and because the degree of duodenal obstruction is often not evident except on barium studies. The rigidity and luminal narrowing of the second portion of the duodenum are typically much more readily apparent on contrast studies than on endoscopy. Duodenal Crohn disease can lead to gastric outlet obstruction. In children, it can be mistaken for annular pancreas.

When duodenal Crohn disease does not respond to medical therapy, gastrojejunostomy with vagotomy is the preferred surgical treatment.^{23,24} Failure to perform a vagotomy may result in marginal ulcer formation and obstruction. Some surgeons have performed duodenal strictureplasty to treat duodenal Crohn disease. The results have been conflicting^{25,26}; the feasibility of this operative approach is limited by the pliability of the duodenum. Many patients experience prompt and full recovery of normal gastric emptying after operation, but some patients with long-standing gastric outlet obstruction continue to experience impaired emptying. The latter may benefit from administration of a prokinetic agent (e.g., metoclopramide or erythromycin).

JEJUNOILEAL DISEASE

Short Bowel Syndrome

Although Crohn disease of the small bowel is not common and accounts for a relatively small proportion of all cases, disease in this area is associated with one of the highest overall recurrence rates. Resection of large portions of the small bowel can result in short bowel syndrome. For this reason, before proceeding with any type of small bowel or ileocolic resection, one should measure the length of the existing small bowel to determine the patient's "bowel resource." One naturally would more readily perform a resection in a patient who has 400 cm of normal small bowel than in one who has only 200 cm.

Resection versus Strictureplasty

The major advance in the surgical treatment of Crohn disease over the past quarter-century has been the technique of small bowel strictureplasty, first proposed by Lee and subsequently popularized by Williams, Fazio, and others.²⁵ Currently, the two most prevalent strictureplasty techniques are Heineke-Mikulicz strictureplasty [see Figure 3] and Finney strictureplasty [see Figure 4]. The former is best suited for

Figure 3 Heineke-Mikulicz strictureplasty. Stay sutures are placed parallel to each other on the antimesenteric border of the bowel over the area of the stricture. (a) The antimesenteric border of the bowel is then opened with the electrocautery over the area of the stricture, and the opening is extended for approximately 1 to 2 cm on either side of the stricture. (b, c) Traction is placed on the stay sutures, and the original longitudinal enterotomy is closed in a horizontal fashion in one or two layers.

strictures up to 5 to 7 cm long [see Figure 5] and the latter for strictures up to 10 to 15 cm long. The side-to-side strictureplasty described by Michelassi and colleagues²⁷ is suitable for longer areas of stricture; however, this technique involves longer suture lines and is mainly considered for patients who already have, or are at high risk for, short bowel syndrome.

The short, isolated strictures characteristic of diffuse jejunoileal Crohn disease are more frequently described in patients with long-standing Crohn disease. It has been postulated that over time, Crohn disease progresses from an edematous condition to a more fibrotic, stricturing condition.²⁸ The fibrotic strictures characteristic of the later stage of the disease are amenable to treatment with strictureplasty. Patients with these short fibrotic strictures typically have obstructive symptoms and often are unable to tolerate solid food, experiencing dramatic weight loss as a result. Although strictureplasty leaves active disease in situ, it usually leads to prompt resolution of obstructive symptoms, regaining of lost body weight, and restoration of normal nutritional status.

Figure 4 Finney strictureplasty. (a) This procedure is suitable for longer areas of stricture (up to 10 to 15 cm). (b) The strictured bowel is bent into the shape of an inverted U. Stay sutures are placed at the apex of the U, which is at the midpoint of the stricture, and at the far ends, which lie 1 to 2 cm proximal and distal to the stricture. A longitudinal enterotomy is made on the antimesenteric border of the bowel with the electrocautery. A side-to-side anastomosis is then performed, with the posterior wall done first. (c) Shown is the completed anastomosis.

Figure 5 Shown is a short fibrotic stricture that is ideally suited to treatment with Heineke-Mikulicz strictureplasty.

A significant concern with strictureplasty is the possibility that small bowel adenocarcinoma may develop; several cases have been reported.^{29,30} I have treated a patient in whom a poorly differentiated jejunal adenocarcinoma developed at the site of a strictureplasty that had been performed 10 years earlier. Accordingly, many surgeons advocate routine biopsy of the active ulcer on the mesenteric side of the bowel at the time of strictureplasty [see Figure 6]. Another concern has to do with the number of strictureplasties that can safely be performed in a single patient in the course of a single operation. As many as 19 strictureplasties have been performed during one procedure without increased morbidity.³¹

Strictureplasty can be performed with either a single-layer or a double-layer anastomosis. It should not be performed in the presence of an abscess, a phlegmon, or a fistula, and like any other anastomosis, it should not be performed proximal to an existing obstruction that is not treated at the time of operation.

Areas of small bowel Crohn disease that are too long to be treated with strictureplasty can be treated with segmental resection. The area to be resected should be as short as possible. There is no need to obtain frozen-section margins to determine the extent of resection; doing so leads to

Figure 6 A large ulcer is nearly always present on the mesenteric luminal border of small bowel strictures.

unnecessary loss of small bowel length.³² The resection should extend into palpably normal areas of small bowel. The easiest way of determining the area to be resected is to feel the mesenteric margin of the bowel until palpably normal tissue is reached. Because Crohn disease is generally more severe on the mesenteric side of the bowel, palpation in this area gives the most accurate impression of the intraluminal character of the bowel. Because it is not uncommon for patients to have multifocal Crohn disease, the entire small bowel should always be inspected at the time of operation. Operating on one area of disease while failing to treat a more proximal lesion is clearly not in the patient's interest.

Because of the high rate of recurrence in patients with isolated small bowel disease, postoperative chemoprophylaxis should be strongly considered. In these patients, I prefer to use a more potent agent, such as an antimetabolite, rather than a 5-ASA agent.

ILEOCOLIC DISEASE

Approximately half of those diagnosed with Crohn disease have ileocolic disease. Ileocolic resection is, in fact, the operation most frequently performed to treat Crohn disease. Currently, there is a trend toward more aggressive medical management of Crohn disease; at the same time, surgeons are seeing more complicated disease at the time of operation. These developments have implications for management. In the large Crohn's Therapy, Resource, Evaluation, and Assessment Tool (TREAT) Registry, prednisone therapy was associated with increased mortality with medical treatment, and narcotic use and therapy were both associated with serious infections with medical therapy, in this case most often infliximab.¹⁴ These are both often given for amelioration of symptoms in patients with obstructing ileocolic disease. An easy ileocolic resection is an experience that a patient generally tolerates well and recovers from very quickly; however, delaying operative management with years of aggressive medical therapy can lead to more complicated disease associated with enteroenteric fistulas, which can be difficult to treat. Ileosigmoid fistulas are among the most common fistulas associated with ileocolic Crohn disease, along with fistulas between the terminal ileum and the ascending colon and fistulas between the terminal ileum and adjacent loops of small bowel.

Disease recurrence is common after ileocolic resection. Colonoscopy is the most accurate modality for postoperative surveillance and the easiest to use; it is more sensitive than either small bowel follow-through or air-contrast barium enema. For this reason, I favor an end-to-end anastomosis after ileocolic resection. In the event of recurrent disease, an end-to-side, side-to-end, or side-to-side anastomosis may be difficult to intubate. There is some evidence in the literature to suggest that the postoperative recurrence rate may be lower with a wider anastomosis.³³ The anastomosis can be performed in either one or two layers. If the bowel is thicker, a handsewn anastomosis is preferred to a stapled one.

The incidence of reoperation for recurrent disease after ileocolic resection is high and increases with the number of resections.³⁴ Postoperative chemoprophylaxis with mesalazine can significantly reduce the recurrence rate.³⁵ Patients who smoke should be strongly encouraged to stop: the rate and severity of recurrence are increased in smokers.²⁶

Special Circumstances

Ileocolic Crohn disease is often associated with intra-abdominal abscesses or fistulas. If an associated abscess is known to be present, CT-guided drainage should be done preoperatively so that a single-stage procedure can then be performed. If an unsuspected abscess is identified at the time of operation, the safest approach is to proceed with bowel resection, perform the posterior wall of the anastomosis, and exteriorize the anastomosis as a loop ileostomy. This loop ileostomy can then be safely closed, often without a formal laparotomy, 8 weeks after operation if there are no signs of ongoing sepsis. If the abscess or the terminal ileal loop is adherent to the sigmoid colon, an ileosigmoid fistula may be present. The decision whether to resect the sigmoid colon is dictated by the appearance and feel of the sigmoid in the involved areas. If only a portion of the anterior colon wall is involved, that portion can be excised in a wedgelike fashion and the excision site closed primarily. If the entire circumference of the sigmoid colon at that point is indurated and woody feeling, a short segmental resection with anastomosis is the best option.

COLONIC DISEASE

Colonic involvement is present in 29 to 44% of patients with Crohn disease.³⁶ One of the challenges in treating colonic Crohn disease is obtaining the correct diagnosis. Whereas Crohn disease of the small bowel is fairly easy to diagnose, colonic disease often is not. Because granulomas are not present in most cases of colonic Crohn disease and because this condition can look very similar to ulcerative colitis both endoscopically and macroscopically, differentiation between Crohn colitis and ulcerative colitis can be difficult in the absence of small bowel or anal disease. Colonic Crohn disease appears to be more frequently associated with cutaneous manifestations (e.g., pyoderma gangrenosum) [see Figure 7].

Indications for Surgical Treatment

The main indications for operative management of colonic Crohn disease are stricture [see Figure 8], malignancy, side effects of medical therapy, and failure of medical therapy. In children, failure to recognize and treat this condition promptly may result in growth retardation. It is important to monitor both bone age and insulinlike growth factor-1 levels. If these are abnormal, timely institution of human growth hormone therapy, operative management of inflammatory bowel disease, or both may still permit normal growth and development.

Side effects of medical therapy can be substantial. They may include such varied complications as aseptic necrosis of the femoral head and cataract formation (both related to steroid use), as well as an increased incidence of opportunistic infections (from immunosuppression secondary to antimetabolite or biologic therapy).³⁷

Failure of medical therapy can refer to continuing severe disease activity or, at worst, to so-called toxic megacolon. The term *toxic megacolon* is actually a misnomer in that not all patients with this condition actually have a true megacolon [see Figure 9a]. In common usage, the term *toxic megacolon* refers to any condition associated with colitis that is severe enough to result in sloughing of the colonic mucosa; such

Figure 7 (a) Shown is pyoderma gangrenosum affecting the peristomal and incisional area 6 months after creation of a loop ileostomy in a 16-year-old girl who had undergone colectomy with ileal pouch-anal anastomosis for a presumed initial diagnosis of ulcerative colitis. (b) Shown is peristomal gangrenosum of the breast in an otherwise asymptomatic patient with Crohn colitis and perianal Crohn disease who had a diverting loop ileostomy.

sloughing permits endotoxins to enter the circulatory system and evoke a septic response. The signs and symptoms of toxic megacolon include those characteristic of sepsis-leukocytosis, fever, tachycardia, and hypoalbuminemia. These patients are very ill and often manifest ileus, which is an ominous

development that frequently signals impending perforation. Emergency surgical intervention is required. At operation, the colon is often distended, and when the specimen is opened, the colon may appear almost autolytic [see Figure 9b]. In this state, the bowel frequently does not hold staples well; accordingly, it is often helpful to sew the distal Hartmann stump between the left and right halves of the anterior inferior rectus fascia at the lower abdominal incision and then to close the skin over it.³⁸ Thus, if the staple line is disrupted, the result is essentially a surgical site infection that can be opened and drained rather than the pelvic abscess [see Figure 9c] that could develop if the rectal stump were located deep within the pelvis.

Types of Disease

Segmental disease In a 2003 review of 92 consecutive cases of patients with Crohn colitis, the number of patients with segmental colonic Crohn disease and the number of those with pancolonic disease were nearly equal.³⁶ Approximately 63% of those with segmental colitis had other disease involvement as well (e.g., jejunoileal, ileocolic, or perianal), compared with only 12% of those with pancolitis. The recurrence rate, however, was higher in patients with segmental colitis than in those with pancolitis. In addition, the risk of recurrence was higher in patients who had granulomatous disease than in those who did not.

Pancolonic disease In cases of pancolonic Crohn disease with associated perianal, jejunoileal, or ileocolic

Figure 8 Shown is a sigmoid colon stricture secondary to Crohn disease that caused obstructing symptoms refractory to medical therapy.

Figure 9 (a) Shown is toxic megacolon in a 17-year-old girl with Crohn colitis. The colon is massively distended and near perforation at the time of operation. (b) When the specimen is opened, it is apparent that large segments of the mucosa have sloughed off, leaving denuded muscle wall. (c) The distal rectosigmoid is incorporated between the left and right halves of the anterior inferior rectus fascia at the lower abdominal incision and placed underneath the skin, which is then closed over it. Thus, in the event of disruption of the distal stump, the contents drain harmlessly through the wound rather than resulting in a pelvic abscess.

involvement, diagnosis is not difficult. However, most patients with Crohn pancolitis do not have other sites of disease involvement, nor do they have granulomas.³⁶ Consequently, differentiation of Crohn pancolitis from ulcerative colitis can be very difficult. Many patients with Crohn disease have been subjected to colectomy with ileal pouch-anal anastomosis (IPAA) because they were initially presumed to have ulcerative colitis.

Operative Procedures

Total proctocolectomy with end ileostomy The traditional procedure for colonic Crohn disease is total proctocolectomy with end ileostomy, which is associated with an 8 to 15% rate of recurrence in the small bowel proximal to the stoma.^{39–41} This operation remains the best choice in patients with severe rectal and anal Crohn disease (e.g., those

with so-called watering-can perineum [see Figure 10a]) and carries the lowest risk of disease recurrence. In contrast to the approach taken in patients with rectal cancer, which involves excising the external anal sphincter and a large portion of the levator muscles, the approach taken in those with colonic Crohn disease is intersphincteric, with dissection performed in the plane between the internal and external anal sphincters to reduce the size of the perineal wound and facilitate healing [see Figure 10b]. Even with the intersphincteric approach, delayed healing of the perineal wound is common, occurring in as many as 30% of patients.

Subtotal colectomy with ileorectal or ileosigmoid anastomosis Because many patients with Crohn disease are young, surgeons have long been interested in operations that do not involve an ileostomy. In the absence of significant

Figure 10 (a) Vessel loops can be used as setons for drainage of abscesses caused by perianal Crohn disease. They can be left in as long as necessary and help prevent recurrent abscess formation. (b) Same patient 6 months following total proctocolectomy.

rectal and anal disease, subtotal colectomy with ileorectal or ileosigmoid anastomosis is an option. Unfortunately, this operation is associated with high recurrence rates (up to 70%)⁴²; however, with the advent of more effective immunosuppressive and biologic therapy, it is hoped that these rates can be reduced. As much palpably normal distal rectum and colon as possible should be spared. The anastomosis can be stapled, although if the bowel wall is thickened, many surgeons would feel more secure with a handsewn anastomosis in either one or two layers.

Segmental resection Currently, more surgeons are advocating colon-sparing procedures for Crohn disease. Although this is a relatively new approach, there have already been some reports documenting the safety of segmental resection in cases of limited disease.⁴³ In patients with colonic strictures resulting in obstruction, segmental resection into palpably normal areas of the bowel yields prompt resolution of symptoms. Because the colon performs an important water-absorbing function, many patients with a limited amount of small bowel can still live without intravenous supplementation if a significant segment of the colon is left in situ. However, patients with segmental Crohn disease appear to have a higher recurrence rate than those with pancolitis, as do patients with granulomas.³⁶ Surgical treatment of Crohn disease continues to undergo reevaluation and reassessment of results on the basis of the availability of newer medical therapies.

Colectomy with IPAA Although colectomy with IPAA is usually not an operation that one would knowingly perform in a patient with Crohn disease, every year many patients undergo this procedure as treatment of colonic inflammatory bowel disease that initially is incorrectly presumed to be ulcerative colitis but later is diagnosed as Crohn disease (on the basis of either final pathologic analysis of the resected specimen or the disease's clinical behavior). Generally

speaking, in the absence of fistulizing disease, most of these patients are able to maintain their pouch, but they require medical therapy for disease control.^{36,44–47} Some surgeons, after very careful patient counseling regarding the real risks of fistulizing disease and other adverse sequelae, will consider IPAA for select patients with Crohn colitis with no evidence of other sites of involvement.⁴⁸

ANAL DISEASE

Types of Disease

With stenosis For patients with anal strictures that are not regularly dilated, the outlook is poor. Such strictures pose functional obstructions and typically lead to continuing problems with fistulas and suppurative disease. They frequently become more and more fibrotic over time and often extend proximally. Most of these patients eventually require fecal diversion. Management generally involves self-dilation, which can often be done with Hegar dilators. If the stenosis is not dealt with, all other treatment of the Crohn disease is doomed to failure; obstruction at the level of the anal canal inevitably results in the persistence of anorectal disease.

Without stenosis Anal Crohn disease without stenosis is much easier to treat medically. Long-term oral metronidazole therapy is often helpful; other medications (e.g., anti-tumor necrosis factor antibody) may be useful as well. Broad fissures are usually asymptomatic. Surgical treatment should be avoided unless the lesions are causing symptoms. Because they tend to have more liquidy bowel movements, patients with Crohn disease need an optimally functioning anal sphincter; hence, fistulotomies, which divide portions of the sphincter, should be avoided if at all possible. Placement of setons through fistula tracts can often prevent abscess formation, provide drainage, and thereby prevent perianal pain while minimizing sphincter trauma. Silk sutures, vessel loops, or Penrose drains also can be used as setons [see

Figure 10]. Although some have reported good results with a collagen fistula plug for Crohn disease,⁴⁹ others, including the author, have not had similarly favorable experiences.^{50,51} Rectovaginal fistulas pose a particular challenge. In the presence of active Crohn disease, advancement flap repair of such fistulas has a low success rate.⁵² Laparoscopically assisted loop ileostomy improves the success rate, but, unfortunately, the fistulas may recur when intestinal continuity is reestablished.

CHEMOPROPHYLAXIS

In 1995, a prospective, randomized study showed that patients who underwent ileocolic resection and were given mesalamine postoperatively had a significant reduction in both the symptomatic and the endoscopic rate of recurrence.³⁵ Not all of the work done since then has confirmed these results, but several studies and a meta-analysis have indicated that mesalamine does reduce the postoperative recurrence rate of Crohn disease.⁵³ Many patients undergoing surgical treatment of Crohn disease are advised to take some type of postoperative preventive medical therapy, either a 5-ASA derivative (e.g., mesalamine) or a stronger immunosuppressive agent (e.g., 6-mercaptopurine or azathioprine). Better studies are required to document the efficacy of the latter agents in preventing recurrence. It is hoped that chemoprophylaxis will reduce the anticipated recurrence rates by 30 to 40%.

SURVEILLANCE

At present, there are no clear guidelines for surveillance after operative treatment of Crohn disease. In my opinion, however, given the increased risk of colorectal cancer in this setting, patients with Crohn disease who retain some colon should undergo colonoscopy every 2 years, not only to detect any development of colonic neoplasia but also to identify any recurrence of disease in a timely manner. If recurrent Crohn disease is detected, appropriate medical therapy should be promptly instituted, with the aim of avoiding subsequent operation if possible.

BEHAVIORAL MODIFICATION

Exposure to cigarette smoke is known to exacerbate the symptoms of Crohn disease. Smoking has been reported to affect the overall severity of the disease, with smokers having a 34% higher recurrence rate and a higher rate of reoperation than nonsmokers.^{54–56} A 1999 study of 141 Crohn disease patients who had undergone ileocolic resection, of whom 79 were nonsmokers and the remainder were smokers, found that the respective 5- and 10-year recurrence-free rates were 65% and 45% in smokers and 81% and 64% in nonsmokers. The recurrence rates were higher in heavy smokers (≥ 15 cigarettes/day) than in moderate smokers.⁵⁷

12 DIVERTICULITIS

John P. Welch, MD, FACS, Jeffrey L. Cohen, MD, FACS, FASCRS, and Rafal Barczak, MD

Diverticula are small (0.5 to 1.0 cm in diameter) outpouchings of the colon that occur in rows at sites of vascular penetration between the single mesenteric taenia and one of the antimesenteric taeniae. At the sites of most diverticula, the muscular layer is absent [see Figure 1]. Technically, such lesions are really pseudodiverticula; true diverticula (which are much less common than pseudodiverticula) involve all layers of the bowel wall. Nevertheless, both pseudodiverticula and true diverticula are generally referred to as diverticula.

The sigmoid colon is the most common site of diverticula: in 90% of patients with diverticulosis, the sigmoid colon is involved.¹ If a diverticulum becomes inflamed as a result of obstruction by feces or hardened mucus or of mucosal erosion, a localized perforation (microperforation) may occur—a process known as diverticulitis. The incidence of diverticulitis has been estimated to be about 10 to 25% in patients with colonic diverticula.¹ Limited prospective data suggest that the risk of developing diverticulitis is low in patients with symptomatic diverticulosis.² Both diverticulosis and variants of diverticulitis may be subsumed under the more encompassing term *diverticular disease*.

The incidence of diverticular disease increases with age. Diverticula are quite common in elderly patients, being

present in more than 80% of patients older than 85 years. Consequently, as the population of the United States continues to age, the overall risk of diverticular complications continues to increase. Before the 20th century, diverticular disease was rare in the United States. By 1996, however, 131,000 patients were being admitted to hospitals with diverticulitis each year.³

A diet containing refined carbohydrates and low-fiber substances, such as is currently widespread in many developed countries (especially in the West), has been associated with the emergence of this disease entity. A low-residue diet facilitates the development of constipation, which can lead to increased intraluminal pressure in the large bowel. In addition, elevated elastin levels are commonly noted at colon wall sites containing diverticula,⁴ and this change causes shortening of the taeniae.¹ High-pressure zones or areas of segmentation may develop [see Figure 2], usually in the sigmoid colon, and diverticula begin to protrude at these locations.⁵ If microperforation of a thin-walled diverticulum takes place, local or, uncommonly, widespread contamination with fecal organisms may ensue. The pericolic tissue (typically, the mesentery and the pericolic fat) thus becomes inflamed, whereas the mucosa tends to remain otherwise normal.

Figure 1 Illustrated are anatomic findings in a segment of colon containing diverticula. Diverticula are located at sites where blood vessels enter the colonic wall.⁸⁷

Figure 2 Depicted is a schematic representation of the process termed segmentation in the colon. It has been theorized that high-pressure compartments lead to the development of diverticula.⁸⁸

Several factors appear to promote the development of diverticular disease and its complications, including decreased physical activity,⁶ obesity,⁷ intake of nonsteroidal antiinflammatory drugs (NSAIDs),⁸ smoking,⁹ and constipation from any cause (e.g., diet or medications). The well-known Western afflictions cholelithiasis, diverticulosis, and hiatal hernia frequently occur together (the Saint triad). Obesity has been associated with the intake of low-fiber diets,¹⁰ and growing numbers of young, obese patients with diverticulitis are being seen by physicians. Consumption of nuts, corn, or popcorn does not increase the incidence of diverticulitis or diverticular bleeding.¹¹

Clinical Evaluation

HISTORY

Uncomplicated (Simple) Diverticulitis

The classic symptoms of uncomplicated acute diverticulitis are left lower quadrant abdominal pain, a low-grade fever, irregular bowel habits, and, possibly, urinary symptoms if the affected colon is adjacent to the bladder. If the sigmoid colon is highly redundant, pain may be greatest in the right lower quadrant. Diarrhea or constipation may occur, together with rectal urgency.

The differential diagnosis includes gynecologic and urinary disorders, perforated colon carcinoma, Crohn disease, ischemic colitis, and, sometimes, appendicitis. Chronic diarrhea, multiple areas of colon involvement, perianal disease, perineal or cutaneous fistulas, or extraintestinal signs are suggestive of

Crohn disease. Rectal bleeding should raise the possibility of inflammatory bowel disease, ischemia, or carcinoma; such bleeding is uncommon with diverticulitis alone. Given the prevalence of diverticula, it is not surprising that colon carcinoma may coexist with diverticular disease [see Figure 3].

Complicated Diverticulitis

Some cases of diverticulitis are classified as complicated, meaning that the disease process has progressed to obstruction, abscess or fistula formation, or free perforation [see Figure 4]. Complicated diverticulitis may be particularly challenging to manage,¹² especially because patients may have no known history of diverticular disease. Lower gastrointestinal (GI) bleeding is also a complication of diverticular disease in 30 to 50% of cases; in fact, diverticula are the most common colonic cause of lower GI bleeding. When diverticular hemorrhage occurs [see 5:6 *Lower Gastrointestinal Bleeding*], it is usually associated with diverticulosis rather than with diverticulitis. Approximately 50% of diverticular bleeding originates in the right colon, despite the low incidence of diverticula in

Figure 3 Barium enema shows a napkin-ring carcinoma (arrow) in the middle of multiple diverticula in a redundant sigmoid colon.

Figure 4 Shown are major complications of diverticular disease of the sigmoid colon.⁸⁹

this segment of the colon. Patients tend to be elderly and to have cardiovascular disease and hypertension. Regular intake of NSAIDs may increase the risk of this complication. Although patients may lose 1 to 2 units of blood, the bleeding usually ceases spontaneously,¹³ and expeditious operative treatment generally is not necessary.

The most common form of complicated diverticulitis involves the development of a pericolic abscess, typically signaled by high fever, chills, and lassitude. Such abscesses may be small and localized or may extend to more distant sites (e.g., the pelvis). They may be categorized according to the Hinchey classification of diverticular perforations,¹⁴ in which stage I refers to a localized pericolic abscess and stage II to a larger mesenteric abscess spreading toward the pelvis [see Figure 5]. On rare occasions, an abscess forms in the retro-peritoneal tissues, subsequently extending to distant sites such as the thigh or the flank. The location of the abscess can be defined precisely by means of computed tomography (CT) with contrast.

Some abscesses rupture into adjacent tissues or viscera, resulting in the formation of fistulas. The fistulas most commonly seen in this setting (50 to 65% of cases) are colovesical fistulas. This complication is less common in women because of the protection afforded by the uterus.

Symptoms of colovesical fistulas tend to involve the urinary tract (e.g., pneumaturia, hematuria, and urinary frequency). Fecaluria is diagnostic of colovesical or enterovesical fistulas. Colovaginal fistulas (which account for 25% of all diverticular fistulas) are usually seen in women who have undergone hysterectomies. The diseased colon is adherent to the vaginal cuff. Most commonly, patients complain of a foul vaginal discharge; however, some patients present with stool emanating from the vagina.

About 10% of colon obstructions are attributable to diverticulitis. Acute diverticulitis can cause colonic edema and a functional obstruction that usually resolves with antibiotic infusion and bowel rest. Stricture formation is more common, usually occurring as a consequence of recurrent attacks of diverticulitis. Circumferential pericolic fibrosis is noted, and marked angulation of the pelvic colon with adherence to the pelvic sidewall may be seen. Patients complain of constipation and narrowed stools. Colonoscopy can be difficult and potentially dangerous in this setting. Differentiating a diverticular stricture from carcinoma may be impossible by any means short of resection.

The term *malignant diverticulitis* has been employed to describe an extreme form of sigmoid diverticulitis that is characterized by an extensive phlegmon and inflammatory

Figure 5 The Hinchey classification divides diverticular perforations into four stages. Mortality increases significantly in stages III and IV.¹⁸

reaction extending below the peritoneal reflection, with a tendency toward obstruction and fistula formation.¹⁵ Malignant diverticulitis is seen in fewer than 5% of patients older than 50 years who are operated on for diverticulitis.¹⁵ The process is reminiscent of Crohn disease, and CT scans demonstrate extensive inflammation. In this setting, a staged resection might be preferable to attempting a primary resection through the pelvic phlegmon. The degree of pelvic inflammation may subside significantly after diversion.¹⁵

A dangerous but rare complication of acute diverticulitis (occurring in 1 to 2% of cases) is free perforation,¹⁶ which includes both perforation of a diverticular abscess throughout the abdomen leading to generalized peritonitis (purulent peritonitis; Hinchey stage III) and free spillage of stool through an open diverticulum into the peritoneal cavity (fecal peritonitis; Hinchey stage IV). The incidence of free perforations may be increasing, at least in the southwestern United States.¹⁷ The overall mortality in this group is between 20 and 30%, that for purulent peritonitis is approximately 13%, and that for fecal peritonitis is about 43%.¹⁶

PHYSICAL EXAMINATION

Uncomplicated Diverticulitis

Physical examination reveals localized left lower quadrant abdominal tenderness with variable degrees of guarding and rebound tenderness. A mass is occasionally felt. The stool may contain traces of blood, but gross bleeding is unusual. Localized inflammation of the perforated diverticulum and the adjacent mesentery is present, and a phlegmon may be seen as well. Depending on the severity of the physical findings, patients may be managed either as inpatients or outpatients.

Complicated Diverticulitis

In a patient with a pericolic abscess, a mass may be detectable on abdominal, rectal, or pelvic examination. In a patient with a colovaginal fistula, a site of granulation tissue and drainage is seen at the apex of the vaginal cuff. In a patient with obstruction, there may be marked abdominal distention, usually of slow onset; abdominal tenderness may or may not be present, but if tears develop in the cecal taeniae, right lower quadrant tenderness is typically seen. In a patient with a free perforation, there is marked abdominal tenderness, usually commencing suddenly in the left lower quadrant and spreading within hours to the remainder of the abdomen. Hypotension and oliguria may develop later. Patients with rectal bleeding usually have no complaints of abdominal pain or tenderness, and they may be hypovolemic and hypotensive, depending on the rapidity of the bleeding.

Investigative Studies

IMAGING

The most useful diagnostic imaging study in the setting of suspected diverticulitis is a CT scan with oral and rectal contrast.¹⁸ Localized thickening of the bowel wall or inflammation of the adjacent pericolic fat is suggestive of diverticulitis; extraluminal air or fluid collections are sometimes seen together with diverticula [see Figure 6]. The most frequent findings (seen in 70 to 100% of cases) are bowel wall thickening, fat stranding, and diverticula.¹⁹ In some cases, small abscesses in the mesocolon or bowel wall are not detected.

Figure 6 Computed tomographic scan shows thickening of the sigmoid colon (arrow) caused by acute diverticulitis.

The diagnosis of carcinoma cannot be excluded definitively when there is thickening of the bowel wall [see Figure 7]. Limited studies show that magnetic resonance imaging has high sensitivity and specificity for acute diverticulitis, and this technique does not expose the patient to ionizing radiation.²⁰

Although CT has tended to replace contrast studies in the evaluation of diverticulitis,¹⁹ the latter may be more useful in differentiating carcinoma from diverticulitis. A contrast study can also be complementary when the CT scan raises the suspicion of carcinoma.¹⁸ When diverticulitis is suspected, water-soluble contrast material should be used instead of barium because of the complications that follow extravasation of barium [see Figure 8 and Figure 9]. Furthermore, in the acute setting, only the left colon should be evaluated. Carcinoma is suggested by an abrupt transition to an abnormal mucosa over a relatively short segment; diverticulitis is usually characterized by a gradual transition into diseased colon over a longer segment, with the mucosa remaining intact. If the contrast study reveals extravasation of contrast outlining an abscess cavity [see Figure 9], an intramural sinus tract, or a fistula, diverticulitis is likely.¹

Colonoscopy is avoided when acute diverticulitis is suspected because of the risk of perforation. It may, however, be done 6 to 8 weeks after the process subsides to rule out other disorders (e.g., colon cancer) [see Figure 10]. When a patient does not respond to therapy, gentle flexible sigmoidoscopy may detect a carcinoma or some other abnormality.^{21,22} If diverticular disease is advanced, the endoscopic procedure may be difficult; the diverticular segment must be fully traversed for the examiner to be able to exclude a neoplasm with confidence. When major lower GI bleeding occurs, colonoscopy is done to search for polyps, carcinoma, or a site of diverticular bleeding. In the case of massive bleeding, selective arteriography is useful for localizing the source, and superselective embolization frequently quells the hemorrhage. The actual risk of bowel ischemia is low when superselective techniques are employed. Bleeding at the time of arteriography may be facilitated by the infusion of heparin or urokinase; however, this is a risky approach that should be taken only

Figure 7 (a) Computed tomographic (CT) scan shows a thickened left colonic wall and diverticulum (arrow). Diverticulitis was considered the most likely diagnosis. (b) CT scan through an adjacent plane shows deformity of the mucosa, suggesting a possible apple-core lesion (arrow). Subsequent endoscopy revealed a carcinoma that was obstructing the colon almost completely.

Figure 8 Contrast study shows local extravasation from the sigmoid colon (arrow); a diverticulum is visible.

when other attempts at localization have failed and recurrent bouts of bleeding have occurred.

When a colovesical fistula occurs, contrast CT with narrow cuts in the pelvis can be very helpful. The classic findings are sigmoid diverticula, thickening of the bladder and the colon, air in the bladder, opacification of the fistula tract and the bladder, and, possibly, an abscess [see Figure 11]. Cystoscopy is less specific, showing possible edema or erythema at the site of the fistula. A contrast enema helps rule out malignant

Figure 9 Shown is extravasation into an abscess cavity (arrow) from diverticulitis at the sigmoid colon–descending colon junction in a postevacuation film.

Figure 10 Colonoscopic view of several sigmoid diverticula reveals no evidence of active diverticulitis (e.g., edema or narrowing).

disease. The diagnostic tests that are most useful for detecting colovaginal fistulas are contrast CT and vaginography via a Foley catheter. Charcoal ingestion helps confirm the presence of colovesical or colovaginal fistulas. On rare occasions, colocutaneous fistulas may develop, causing erythema and breakdown of the skin. Colouterine fistulas may occur as well; these are also quite rare.

Management

MEDICAL

Uncomplicated diverticulitis is usually managed on an outpatient basis by instituting a liquid or low-residue diet and administering an oral antibiotic combination that covers

anaerobes and gram-negative organisms (e.g., ciprofloxacin with metronidazole or clindamycin) over a period of 7 to 10 days. Provided that symptoms and signs have subsided, the colon may be evaluated more fully several weeks later with a contrast study or colonoscopy if the diagnosis of diverticular disease has not already been established. If symptoms worsen, hospitalization should be considered. Over the long term, patients should be maintained on a high-fiber diet, although it may take months for the diet to have an effect on symptoms. Limited trials suggest that other substances such as probiotics and antiinflammatory agents such as mesalazine may help prevent recurrent attacks.^{23,24}

If more significant physical findings and symptoms of toxicity develop, hospitalization is warranted [see Figure 12]. Patients are placed on a nihil per os (NPO) regimen, and intravenous fluids and antibiotics are administered (e.g., a third-generation cephalosporin with metronidazole) until abdominal pain and tenderness have resolved and bowel function has returned. As a rule, resolution occurs within several days. If there is clinical evidence of intestinal obstruction or ileus, a nasogastric tube is placed. In most cases, ileus-related symptoms resolve with antibiotic treatment. CT scans are useful for establishing the correct diagnosis in the emergency department²⁵; furthermore, the severity of diverticulitis on CT scans predicts the risk of subsequent medical failure. Following the sedimentation rate may be helpful in assessing the effectiveness of treatment. Most patients recover with conservative management alone. By observing early trends in the leukocyte count and the maximum temperature in patients with acute diverticulitis, one can predict whether they will recover quickly as expected or if they will likely require prolonged intravenous antibiotics and/or an operation.²⁶ It has been estimated that 15 to 30% of patients admitted with acute diverticulitis will require surgical treatment during the same admission.¹

If fever and leukocytosis persist despite antibiotic therapy, the presence of an abscess should be suspected. Small (< 5 cm) abscesses may respond to antibiotic infusion and bowel rest. Larger abscesses that are localized and isolated may be accessible to percutaneous drainage [see Figure 13].²⁷ Generally, this technique is reserved for abscesses greater than 5 cm in

Figure 11 (a) Computed tomographic (CT) scan in a patient with a colovesical fistula shows air in the thickened tract (arrow) adjacent to the sigmoid colon. (b) CT scan through an adjacent plane shows air in the bladder (arrow) as a result of the fistula. No contrast is present in the bladder.

diameter in low-risk patients who are not immunocompromised. It often leads to resolution of sepsis and the resulting symptoms and signs (e.g., abdominal pain and tenderness and leukocytosis), usually within 72 hours, thereby facilitating subsequent elective surgical resection of the colon. In addition, percutaneous drainage offers cost advantages in that it reduces the number of operative procedures required and shortens hospital stay.²⁸ Patients with severe comorbidities at times can be managed with drainage alone.²⁹

Access to a pelvic collection may be difficult to obtain, and the drainage procedure typically must be done with the patient in a prone or lateral position. If the catheter drainage amounts to more than 500 mL/day after the first 24 hours, a fistula should be suspected. Before the catheter is removed, a CT scan is done with injection of contrast material through the tube to determine whether the cavity has collapsed. If this approach fails (as it usually does in patients with multiple or multiloculated abscesses), an expeditious operation may be necessary.¹⁷ An initial surgical procedure is required in about 20% of cases.

SURGICAL

Overall, approximately 20% of patients with diverticulitis require surgical treatment.³⁰ Most surgical procedures are reserved for patients who experience recurrent episodes of acute diverticulitis that necessitate treatment (inpatient or outpatient) or who have complicated diverticulitis. The most common indication for elective resection is recurrent attacks—that is, several episodes of acute diverticulitis documented by studies such as CT. Rerrecurrences may be more common than recurrences.³¹ In 2000, a task force of the American Society of Colon and Rectal Surgeons recommended sigmoid resection after two attacks of diverticulitis.³² A subsequent cost analysis using a Markov model suggested that cost savings could be achieved if resection was done after three attacks.³³ There is a growing tendency to question arbitrary guidelines for surgical management of recurrent attacks, with the exception of certain groups, such as immunocompromised patients.^{34,35} Current practice guidelines state that the recommendation to perform elective sigmoid resection after recovery from uncomplicated acute diverticulitis should be made on a case-by-case basis. The decision-making process should be influenced by the age and medical condition of the patient, the frequency and severity of attacks, and the presence of symptoms after the acute attack. Elective resection is generally recommended after an episode of complicated diverticulitis.³⁶ Efforts are made to time surgical treatment so that it takes place during a quiescent period 8 to 10 weeks after the last attack. Barium enema or colonoscopy may be employed to evaluate the diverticular disease and rule out carcinoma. The bowel can then be prepared mechanically and with antibiotics (e.g., oral neomycin and metronidazole on the day before operation).

Elective resection is a common sequel to successful percutaneous drainage of a pelvic abscess in an otherwise healthy, well-nourished patient.³⁷ The timing of surgery may be guided by the extent of the inflammatory changes (as documented by CT scanning) and the patient's clinical course. Most patients can be operated upon within 6 weeks. Elective resection is the preferred approach to diverticular fistulas as well. Colovesical fistulas are usually resected because of the risk of urinary sepsis and the concern that a malignancy might be overlooked.

Preferably, the operation is done when the acute inflammation has subsided.

Elective resection is done via either the open route or, increasingly, the laparoscopic route.³⁸ The learning curve for laparoscopic colectomy is 20 to 50 cases.³⁹ Obese patients with severe colonic inflammation are poorer candidates for laparoscopic resection.³⁸ In our institution, the development of hand-assisted procedures has widened the opportunities for using minimally invasive surgery [see 5:32 *Procedures for Diverticular Disease*], allowing all types of diverticular resections to be performed more safely.^{40,41} Hand-assisted laparoscopic sigmoidectomy for diverticular disease is associated with lower conversion rates and shorter operative times when compared with purely laparoscopic surgery.⁴² In addition, the hand-assisted approach affords a better opportunity to complete complicated cases in a minimally invasive fashion.^{2,43} Minimally invasive procedures have several advantages over conventional procedures: decreased intraoperative trauma, fewer postoperative adhesions, reduced postoperative pain, shorter duration of ileus, quicker discharge from the hospital, and earlier return to work.⁴⁴ Such procedures can be done safely in obese patients,⁴⁴ and the conversion rate is now low.^{39,44,45} The technical details of the procedures are addressed elsewhere [see 5:32 *Procedures for Diverticular Disease*].

Some patients with complicated diverticulitis require emergency resection because of free perforation and widespread peritonitis. In such patients, the American Society of Anesthesiologists (ASA) physical status score and the degree of preoperative organ failure may be significant predictors of outcome.⁴⁶ Unfavorable systemic factors (e.g., hypotension, renal failure, diabetes, malnutrition, immune compromise, and ascites) play a vital role in determining patient outcome,⁴⁶ as does the severity of the peritonitis (i.e., extent, contents, and speed of development). One of the unfortunate limitations of the Hinchey classification is that it does not take comorbidities into account. Because the bowel is not prepared before operation, the surgeon may feel uncomfortable doing an anastomosis. On-table lavage may be considered if contamination is minimal, but it adds to the time spent under anesthesia during an emergency procedure.

As a general rule, resection and immediate anastomosis (open or laparoscopic)⁴⁵ are suitable for Hinchey stage I and perhaps stage II diverticular perforations, whereas resection with diversion (the Hartmann procedure) is the gold standard for stage III and especially stage IV.⁴⁷ This recommendation is based on the finding that an anastomosis involving the left colon is risky when performed under emergency conditions.⁴⁸ The once-popular three-stage procedures are now of historical interest only. There are some reports of successful outcomes for type III and type IV cases after extensive abdominal lavage and two-layer anastomoses⁴⁹ or after on-table lavage of the colonic contents to allow primary anastomosis.⁵⁰ There have been a number of recent reports of laparoscopic peritoneal lavage and intraperitoneal drainage for the treatment of purulent peritonitis (Hinchey III) scenarios. Morbidity has been low, and a delayed laparoscopic sigmoid resection has been possible.^{51,52} Grading of comorbidities with classification systems such as APACHE II or the Mannheim peritonitis index can facilitate decision making with respect to the question of anastomosis versus diversion.^{53,54} The surgeon's decision must be individualized on the basis of each patient's

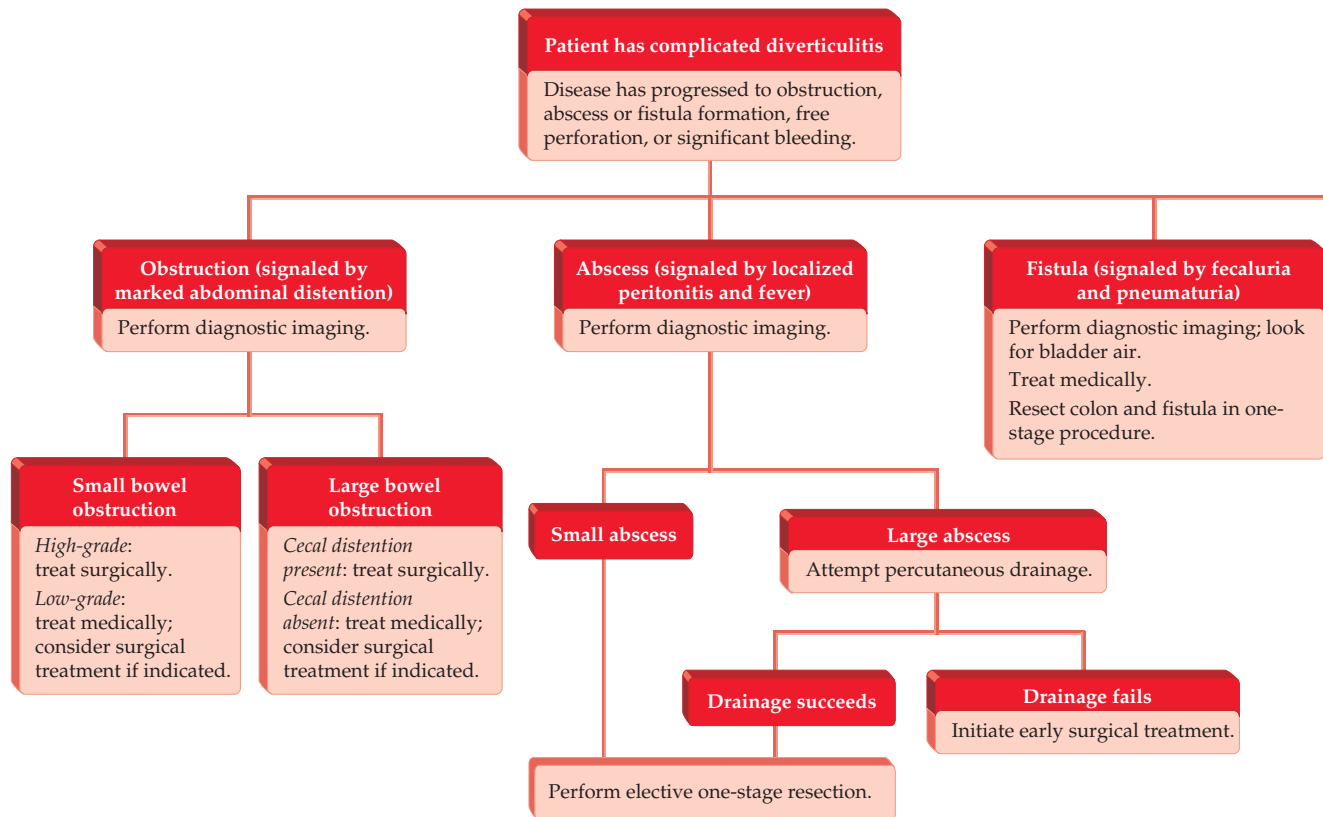

Figure 12 Algorithm outlining treatment options for complicated diverticulitis. GI = gastrointestinal; RBC = red blood cell.

Figure 13 (a) Computed tomographic scan shows a pericolic abscess (arrow) caused by a contained perforation arising from sigmoid diverticulitis. (b) A pigtail catheter (arrow) has been placed into the abscess cavity by the interventional radiologist.

condition and needs. The literature on this topic is confusing in that most of the published reports are small and retrospective, with only limited classification of disease severity.

Currently, surgeons encountering acute diverticulitis are more likely to do one-stage resections, as opposed to Hartmann procedures, than they once were.^{46,55,56} The advantage of the

one-stage approach is that the colostomy takedown, frequent postoperative complications,⁵⁷ and attendant 4% mortality are avoided.⁵⁸ Furthermore, at least 30% of patients who undergo a Hartmann procedure never return for colostomy closure. A primary anastomosis can be protected with a proximal ileostomy as well.^{47,59} Transverse colostomy and loop ileostomy

appear to be equally safe, although skin changes may be more problematic after a colostomy,⁶⁰ and an ileostomy closure tends to be less complex than a colostomy closure. On-table lavage may also be used as an adjunct to anastomosis.

The risk of complications inherent in operations on the colon should always be kept in mind, especially in the relatively few patients undergoing emergency procedures.^{61,62} In this setting, the bowel is unprepared and systemic sepsis may be present. Potential complications include ureteral injuries; anastomotic leakage, anastomotic stricture, and postoperative intra-abdominal abscesses; perioperative bleeding involving the mesentery, adhesions, the splenic capsule, or the presacral venous plexus; postoperative small bowel obstruction; stomal complications; wound infection, wound dehiscence, and abdominal compartment syndrome; acute respiratory distress syndrome; and multiple organ dysfunction syndrome. Even after successful operations, some patients continue to have abdominal pain attributable to factors such as irritable bowel syndrome.^{63,64}

Large bowel obstruction secondary to diverticulitis can lead to considerable morbidity and may necessitate surgical intervention.⁵⁹ The obstruction is usually partial [see Figure 14 and Figure 15], allowing preparation of the bowel in many cases. High-grade obstruction represents a complex problem. If the cecum is dilated to a diameter of 10 cm or greater and there is tenderness in the right lower quadrant, expeditious surgery is necessary because of the risk of cecal necrosis and perforation. High-grade obstruction with fecal loading of the colon is usually

Figure 14 Computed tomographic scan shows marked thickening of the sigmoid wall (arrows) in a patient with diverticular disease who presented with symptoms of intractable constipation. No contrast is present in the lumen (curved arrow).

managed by performing a Hartmann procedure, although on-table lavage may be considered.¹⁷ A survey of GI surgeons in the United States indicated that 50% would opt for a one-stage procedure in low-risk patients with obstruction, whereas 94% would opt for a staged procedure in high-risk patients.⁶⁵

Figure 15 Contrast study shows high-grade retrograde obstruction, multiple diverticula, and a long proximal sigmoid stricture. A tiny extraluminal tract (possibly intramural) from a diverticulum (arrow) is seen.

Small bowel obstruction may also complicate the clinical picture. Mechanical small bowel obstruction may occur as a consequence of adherence of the small bowel to a focus of diverticulitis, especially in the presence of a large pericolic abscess. Whereas small bowel obstruction tends to cause periumbilical crampy abdominal pain and vomiting, these characteristic manifestations may be obscured in part by pain attributed to diverticulitis. The concern in this situation is that ischemic small bowel may be ignored, with potentially disastrous consequences. Diarrhea should trigger the suspicion of colonic disease, and formation of a fistula into the small bowel should raise the possibility of Crohn disease. CT scanning often helps the surgeon differentiate between primary and secondary small bowel obstruction, but, ultimately, exploratory surgery may be required for both diagnosis and treatment.

Lower GI bleeding caused by diverticular disease rarely calls for emergency resection because the bleeding is self-limited in most patients (80 to 90%). Furthermore, active diverticulitis is rare when active bleeding is the presenting symptom. Attempts are made to establish the active bleeding site by means of colonoscopy,⁶⁶ tagged red blood cell nuclear scans, or angiography; barium contrast studies have no role to play in this situation. Emergency resection is indicated if the bleeding is life-threatening and if colonic angiography and attempted superselective embolization prove unsuccessful. In an unstable patient, total abdominal colectomy is necessary if the site of bleeding is unknown, although identification of the bleeding site with intraoperative colonoscopy has been reported. In a stable patient with ongoing bleeding, repeat

angiography at a later time is appropriate, or so-called phar-macoangiography (infusion of heparin) can be employed in an attempt to induce bleeding.

Special Types of Diverticulitis

CECAL DIVERTICULITIS

In the United States, diverticulitis rarely involves the cecum or the right colon. Right-side diverticula occur in only 15% of patients in Western countries, compared with 75% in Singapore.¹ The incidence of cecal diverticulitis appears to be related to the number of diverticula present.⁶⁷ A classification system has been proposed that divides cecal diverticulitis into four grades [see Figure 16] to facilitate comparisons between different clinical series and to help surgeons formulate treatment plans in the operating room.⁶⁷ Some cecal diverticula are true diverticula, containing all layers of the bowel wall, but the majority are pseudodiverticula. Diverticulitis of the hepatic flexure and the transverse colon is even less common and can present with symptoms suggesting appendicitis.⁶⁸

Patients with right-side disease tend to be younger and to have less generalized peritonitis than patients with left-side diverticulitis.^{67,68} Because they typically present with right lower quadrant pain, fever, and leukocytosis, acute appendicitis is usually suspected. CT scans are helpful for differentiating cecal diverticulitis from appendicitis or colon cancer [see Figure 17].⁶⁹ If cecal diverticulitis is suspected (as in a patient who has previously undergone appendectomy or in a patient with known right-side diverticulosis who has experienced similar attacks in the past), medical management with observation and antibiotics is generally the favored strategy, just as with simple sigmoid diverticulitis. In Japan, where right-side diverticulitis is more common, medical treatment has been successfully used for recurrent attacks of uncomplicated right-side diverticulitis.⁷⁰ After a few weeks, colonoscopy should be performed to rule out a colonic neoplasm.

If the patient has significant peritonitis or the diagnosis is unclear, laparoscopy or laparotomy is indicated. It is important that one or the other be done because the mortality associated with delayed treatment of perforated cecal diverticulitis is high. In our institution, laparoscopy is usually employed; if the diagnosis is unclear, laparotomy is recommended. When inflammation is localized and minimal, colectomy is unnecessary, and incidental appendectomy should be considered if the cecum is uninvolved at the base of the appendix.⁷¹ If desired, the diverticulum may be removed as well.

Diverticulectomy should be done only if (1) carcinoma can be ruled out, (2) the resection margins are free of inflammation, (3) the ileocecal valve and the blood supply of the bowel are not compromised, and (4) perforation, gangrene, and abscess are absent.⁶⁷ Localized diverticulectomy, in general, should be reserved for grade I and grade II disease.⁶⁷ Sometimes, the ostium of the inflamed diverticulum is palpable if the cecum is mobilized surgically. On-table cecocolonoscopy through the appendiceal stump has also been helpful in establishing the diagnosis in the operating room.⁷¹ Grade III and IV cecal diverticulitis may be difficult to differentiate from carcinoma; resection is favored for these lesions. An anastomosis may be created if contamination is limited, but, generally, primary resection, ileostomy, and a mucous fistula are favored for treatment of grade IV disease.

Figure 16 Illustrated is a proposed classification of pathologic types of cecal diverticulitis. Grade I is a specific inflamed diverticulum; grade II is a cecal mass; grade III is characterized by a localized abscess or fistula; and grade IV represents a free perforation or a ruptured abscess with peritonitis.⁵⁹

DIVERTICULITIS IN YOUNG PATIENTS

Diverticulitis in patients younger than 40 years has been a focus of considerable attention in the literature, although this group represents only about 2 to 5% of the patients in large series.³² The incidence of diverticulitis in young patients may be increasing, and obese Latino men appear to be at particular risk.⁷² This predominance in males reflects a tendency to underdiagnose acute diverticulitis in young women.⁷³ Some authors have asserted that diverticulitis is particularly virulent in young patients; however, current data tend not to support this concept, suggesting that patients with mild diverticulitis are misdiagnosed when hospitalized or are treated as outpatients. The high rate of early operation in young patients probably reflects misdiagnosis of diverticulitis as acute appendicitis rather than the development of particularly severe forms of diverticulitis.⁷² Patients found to have uncomplicated acute diverticulitis may, if desired, undergo incidental appendectomy in conjunction with medical treatment of diverticulitis.

Figure 17 Computed tomographic scan shows inflammation in the pericecal area (arrow) and cecal edema, which could represent cecal diverticulitis. Because the appendix is not clearly visualized, appendicitis cannot be ruled out.

Unlike elderly patients, hospitalized young patients with diverticulitis tend to have few comorbidities other than obesity. Furthermore, young patients hospitalized for diverticulitis tend to have relatively advanced disease, perhaps as a consequence of delayed diagnosis, whereas elderly patients hospitalized with an admitting diagnosis of diverticulitis tend to exhibit a wider spectrum of disease severity. Young patients appear not to have a higher rate of recurrent diverticulitis than older patients do; thus, aggressive resection is not necessary at the time of the first attack.⁷² However, a finding of advanced diverticulitis on CT scans is a predictor of subsequent disease complications in this population.⁷⁴

In general, diverticulitis should be approached in the same fashion in younger patients as in older patients.⁷⁴ The pathophysiology of the disease is probably identical. As in the elderly, elective resection is recommended after recurrent attacks, not after a single attack; with follow-up, the majority of patients hospitalized with acute diverticulitis do not require operation.^{34,74–76}

DIVERTICULITIS IN IMMUNOCOMPROMISED PATIENTS

In view of their known predisposition to infection, immunocompromised patients (e.g., chronic alcoholics, transplant patients, and persons with metastatic tumors who are receiving chemotherapy) with diverticulitis are at particular risk.⁷⁷ There is no evidence that the incidence of diverticulitis is higher in this population than in the general population, but it is clear that immunocompromised patients have higher rates of operation once diverticulitis develops and that their postoperative mortality is higher.⁷⁸ Corticosteroid intake causes a number of significant problems, such as thinning of the colonic wall, lessening of the physical findings with diverticulitis, and an attenuated inflammatory response.

Any immunocompromised patient with abdominal pain should be evaluated aggressively. Contrast-enhanced CT is the imaging study of choice. The risk of perforation is increased in this setting, as is the risk of postoperative complications such as wound dehiscence. For an immunocompromised patient who has recovered from an episode of symptomatic diverticulitis, elective surgical treatment is recommended. A renal transplant patient with asymptomatic diverticulosis, however, need not undergo prophylactic colectomy. Pretransplantation colonic screening of patients older than 50 years does not reliably predict posttransplantation colonic complications.⁷⁹

ATYPICAL PRESENTATIONS

Diverticulitis may give rise to various unusual manifestations involving multiple organ systems [see Table 1]. Not surprisingly, immunocompromised patients are at particular risk.

Retroperitoneal abscesses can track into anatomic planes (e.g., along the psoas muscle) or through the obturator foramen to areas such as the neck, the thigh, the knee, the groin, and the genitalia. CT scanning is essential to outline the extent of such abscesses. Contrast enemas show the diverticula along with a sinus tract into the abscess cavity. Cultures of the abscess demonstrate the presence of colonic organisms

Table 1 Unusual Extra-Abdominal Presentations of Diverticulitis⁹⁰

Dermatologic	Pyoderma gangrenosum
Urinary	Ureteral obstruction Coloureteral fistula
Soft tissue	Thigh abscess Necrotizing fasciitis
Orthopedic	Osteomyelitis Arthritis
Gynecologic	Colouterine fistula Ovarian tumor/abscess
Genital	Epididymitis Pneumoscrotum
Neurologic	Coloepidural fistula
Vascular	Femoral vein thrombosis Mesenteric vein thrombosis Pylephlebitis Colovenous fistula
Perineal	Fournier gangrene Complex anal fistula

such as *Bacteroides fragilis*. Definitive treatment consists of wide abscess drainage and colon resection. Without aggressive surgical management, mortality is high.

The protean manifestations of diverticulitis also include pylephlebitis (which causes liver abscesses), arthritis, and skin changes. Diverticulitis has, in fact, replaced appendicitis as the most common source of liver abscesses of portal origin. Simple abscesses may be drained percutaneously if they are not too large, and multiple loculated abscesses may be managed with open drainage. The main risk factors for mortality from liver abscesses are immunosuppression, underlying malignancy, the presence of multiple organisms, and liver dysfunction. If the decision is made to perform a colectomy, the procedure may be done after drainage of the liver abscess or simultaneously with drainage during an open procedure.

GIANT DIVERTICULA

An anatomic curiosity sometimes encountered in patients with diverticular disease is a giant diverticulum, also termed a giant gas cyst or a pneumocyst of the colon.⁸⁰ These lesions, which may reach diameters of 40 cm, are believed to develop as a consequence of a ball-valve mechanism created by intermittent occlusion of the neck by fecal material that traps air in the diverticulum. Most giant diverticula are minimally symptomatic, causing only mild abdominal pain, and perforation is rare. A mobile mass may be palpable, and the gas-filled cyst can be seen on plain abdominal films. As many as two thirds of giant diverticula are opacified during a barium enema and can thereby be differentiated from other abnormalities (e.g., a mesenteric cyst, emphysematous cholecystitis, or a colon duplication) [see Figure 18]. The cyst tends to adhere densely to adjacent structures (e.g., the bladder and the small bowel). The treatment of choice is resection of the colon and the cyst; performing diverticulectomy alone can lead to the development of a colocutaneous fistula.

Figure 18 Giant sigmoid diverticulum opacified during a barium enema examination.⁸⁰

RECURRENT DIVERTICULITIS AFTER RESECTION

Recurrent diverticulitis is rare after a colectomy for diverticulitis, occurring in 1 to 10% of patients.⁸¹ As many as 3% of patients who have undergone resection for diverticulitis will require repeat resection. The differential diagnosis includes Crohn disease, irritable bowel syndrome, carcinoma, and ischemic colitis. CT and colonoscopy should be carried out. Particular care should be taken to review pathologic specimens for evidence of Crohn disease.

The only significant determinant of recurrent diverticulitis is the level of the anastomosis; the high pressure in the sigmoid colon distal to the anastomosis appears to be responsible.

In one study, the risk of recurrence was four times greater in patients with a colosigmoid anastomosis than in those with a colorectal anastomosis.⁸² Reoperation requires a dissection that commences in noninflamed tissue. Dissection may be particularly difficult near the pelvic sidewall because of fibrosis; ureteral stenting may facilitate identification of the ureters.

SUBACUTE AND ATYPICAL DIVERTICULITIS

A small number of patients experience recurrent episodes of left lower quadrant abdominal pain that are not accompanied by the classic findings of acute diverticulitis (e.g., fever and leukocytosis). The inflammatory changes associated with diverticula in this subgroup have been referred to as atypical, subacute, or smoldering diverticulitis.^{83,84} In this setting, there is not always a direct association between endoscopic and clinical findings; endoscopic evidence of diverticular inflammation has been seen in asymptomatic patients.⁸⁵ It has been suggested that there is a relation between diverticular disease and colitis.⁸⁶ Patients with chronic lower abdominal pain should undergo imaging studies and endoscopic evaluation, and other disorders (e.g., irritable bowel syndrome, inflammatory bowel disease, drug-induced symptoms, and bowel ischemia) should be excluded. In most cases of atypical diverticulitis, endoscopic findings are normal.⁸⁴ In carefully selected patients, colectomy often eliminates the abdominal pain, and many of these patients are eventually found to have histologic signs of acute and chronic mucosal inflammation.⁸⁴

Financial Disclosures: None Reported.

13 FULMINANT ULCERATIVE COLITIS

Roger Hurst, MD, Sharon L. Stein, MD, and Fabrizio Michelassi, MD

Fulminant ulcerative colitis is a potentially life-threatening disorder that requires expert management to allow for optimal outcomes. Once associated with very high mortality,¹ the medical and surgical treatment of fulminate ulcerative colitis has greatly improved such that mortality from fulminant ulcerative colitis currently is less than 3%.^{2,3} Optimal management necessitates coordination between medical and surgical therapy; hence, multidisciplinary strategies are required.

Disease Definition

The most commonly applied classification for the severity of ulcerative colitis was described by Truelove and Witts, who identified clinical parameters to categorize mild, moderate, and severe colitis.⁴ The Truelove-Witts classification, however, does not specify a unique category for fulminant disease. Hanauer modified this classification scheme to include the designation of fulminant colitis [see Table 1].⁵ There is, however, no universally agreed-upon distinction between severe and fulminant ulcerative colitis.⁶ Some authors use the

terms “severe” and “fulminant” interchangeably, whereas others, concerned over the lack of a clear definition, recommend that the term “fulminant ulcerative colitis” be avoided.⁷ This recommendation aside, the term “fulminant ulcerative colitis” is an established component of the medical vernacular even if the term itself is not clearly defined.^{8–10} Fulminant ulcerative colitis is certainly a severe condition associated with systemic deterioration related to progressive ulcerative colitis. Most would agree that a flare of ulcerative colitis can be considered fulminant if it is associated with one or more of the following: high fever, tachycardia, profound anemia requiring transfusion, dehydration, low urine output, abdominal tenderness with distention, and profound leukocytosis with left shift, severe malaise, or prostration. Patients with these symptoms should be hospitalized for aggressive resuscitation while clinical assessment and treatment are initiated.¹¹

Clinical Assessment

Patients admitted with severe or fulminant ulcerative colitis require a complete history and physical examination. Fulminant ulcerative colitis is rarely the initial presentation of ulcerative colitis, and most patients will have a prior diagnosis. The abdominal examination should focus on signs of peritoneal irritation that may suggest perforation or abscess formation. Any patients admitted with severe ulcerative colitis may have already received substantial doses of corticosteroids, which can mask the physical findings of peritonitis.

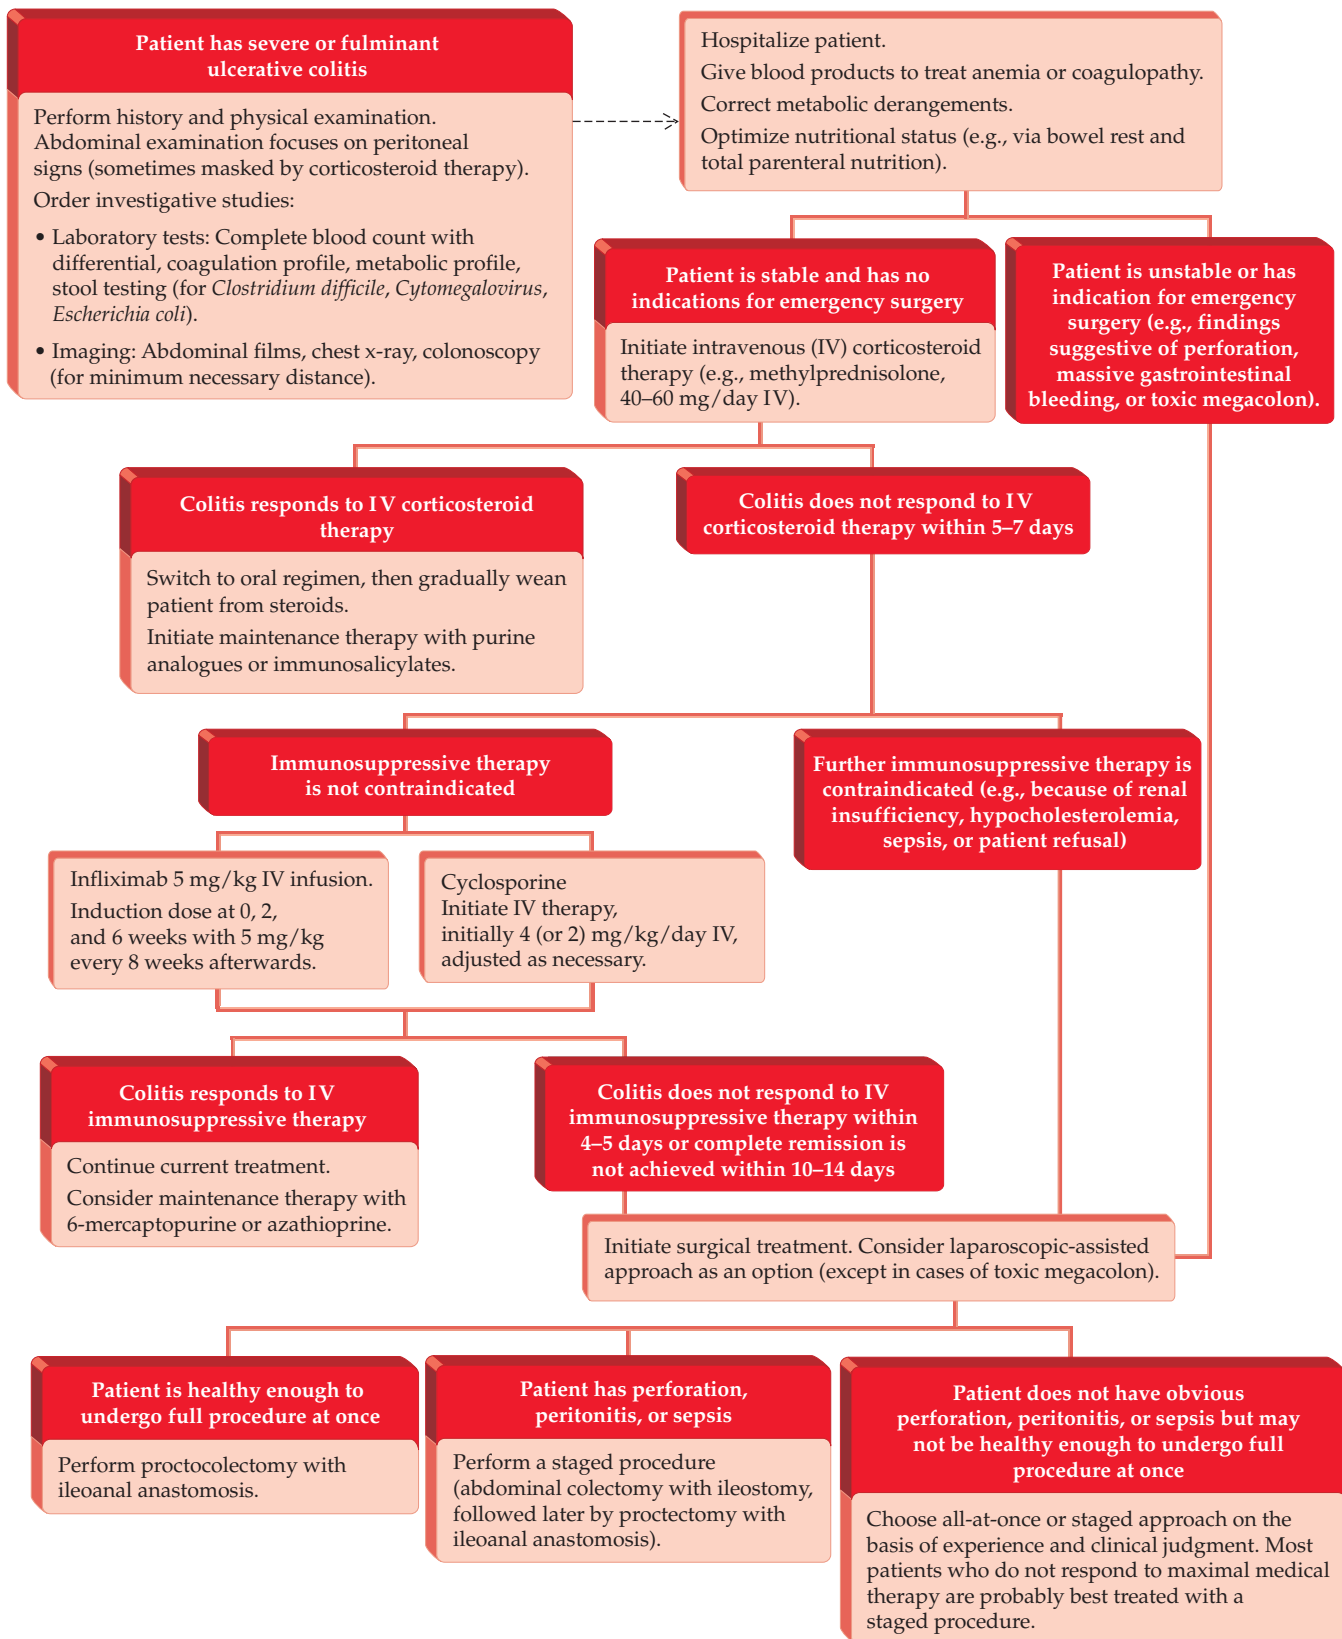

Initial laboratory studies should include a complete blood count with differential, a coagulation profile, and a complete metabolic profile with assessment of nutritional parameters such as the serum albumin. Abdominal films and an upright chest x-ray should be obtained to assess for colonic distention indicating toxic megacolon and to assess for the presence of pneumoperitoneum indicating perforation. Infectious agents should be ruled out by multiple stool specimens sent for *Clostridium difficile*, cytomegalovirus, and *Escherichia coli* O157:H7.^{12,13} It is important to identify the presence of opportunistic infections, particularly *C. difficile*, even in patients with an established diagnosis of ulcerative colitis, as superinfection with *C. difficile* in ulcerative colitis patients is common. Assessment with endoscopic examination of the

Variable	Mild Disease	Severe Disease	Fulminant Disease
Stools (no./day)	< 4	> 6	> 10
Blood in stool	Intermittent	Frequent	Continuous
Temperature (°C)	Normal	> 37.5	> 37.5
Pulse (beats/min)	Normal	> 90	> 90
Hemoglobin	Normal	< 75% of normal value	Transfusion required
Erythrocyte sedimentation rate (mm/hr)	≤ 30	> 30	> 30
Colonic features on radiography	—	Air, edematous wall, thumb printing	Dilatation
Clinical signs	—	Abdominal tenderness	Abdominal distention and tenderness

Management of Fulminant Ulcerative Colitis

Figure 1 Sigmoidoscopy demonstrating deep ulcerations in a patient suffering from fulminant ulcerative colitis.

colon and rectum in the face of fulminant ulcerative colitis is controversial.¹⁴⁻¹⁶ Colonoscopy with biopsy can provide useful diagnostic information. Reports indicate that in experienced hands, colonoscopy can be performed in patients with severe colitis with little risk.^{14,15} In general, however, it is recommended that endoscopic examination be limited to the minimum distance necessary to confirm severe colitis. If an endoscopic examination is to be performed, it is important to minimize the amount of air insufflation as overdistention of the colon may lead to perforation or the development of megacolon. Typical endoscopic findings in fulminant ulcerative colitis are severe inflammation, ulcerations, and mucosal sloughing. Colitis typically is worst in the rectum and continues proximally in a contiguous fashion. Occasionally, the distal rectum may be spared secondary to the use of topical medications such as steroid suppositories. Although these findings help differentiate ulcerative colitis from Crohn disease and indeterminate colitis, the differentiation is probably not important in the setting of fulminant disease, where maximal medical therapy or surgical treatment with subtotal colectomy will be the same regardless of diagnosis. Beyond the diagnostic information, endoscopy can provide useful prognostic information. Carbonell and colleagues noted that the presence of deep extensive colonic ulcerations indicates a low probability for successful medical treatment of fulminant ulcerative colitis, with less than 10% of patients with deep ulcers responding to medical treatment.¹⁴ Such an endoscopic finding thus may assist in the decision to proceed with early surgery if medical therapy does not show rapid and significant improvement [see Figure 1].

General Care

All patients with fulminant ulcerative colitis require hospitalization. Blood products should be administered to treat significant anemia or coagulopathy. Metabolic derangements should be corrected.¹⁷ Patients with perforation or massive lower gastrointestinal hemorrhage need emergent operative treatment. More stable patients are initially managed with

medical therapy. Narcotics, antidiarrheal agents, and other anticholinergic medications should be avoided as they can precipitate toxic dilation of the colon. Bowel rest typically reduces the volume of diarrhea, but it is not yet clearly established if bowel rest affects the clinical course of the fulminant colitis.^{18,19} McIntyre and colleagues reported no significant change in outcome in patients with acute flares of ulcerative colitis managed with total parenteral nutrition (TPN) and bowel rest compared to patients taking enteral nutrition.¹⁹ This study, however, involved varying degrees of severity of colitis such that only a small number of patients with fulminant ulcerative colitis appear to have been included in the study. Conversely, Mikkola and Jarvinen reported a potential clinical advantage to bowel rest and TPN in patients suffering from fulminant ulcerative colitis.¹⁸ The most common approach is to initially place these patients on bowel rest with hyperalimentation. Oral feedings are initiated once symptoms of the fulminant attack begin to improve. Whether patients are maintained on bowel rest or given oral feeds, each patient should always receive adequate nutritional support; hence, TPN should be maintained until the patient is tolerating full enteral feedings.

Medical Therapy

The main standard medical therapy for fulminant ulcerative colitis involves the induction of remission with intravenous (IV) corticosteroids or biologics followed by long-term maintenance treatment in the form of purine analogues or biologics for those patients who achieve remission. Cases that are unresponsive to IV steroids are considered for IV cyclosporine and, more recently, infliximab.

STERIODS

Steroid treatment has been the frontline therapy for acute flares of ulcerative colitis for almost 50 years. Response rates for cases of fulminant ulcerative colitis fall in the range of 50 to 60% when steroids are given over a 5- to 10-day course of treatment.^{20,21} Methylprednisolone in a dose of 40 to 60 mg per day, given as a continuous IV infusion, is a common regimen.^{5,22-24} The duration of treatment to allow for response from IV steroid therapy has been controversial. Truelove and Witts in 1955 recommended urgent surgery after 5 days if the patient has not responded to IV steroid therapy.⁴ This 5-day rule has been widely adopted, but experience suggests that courses up to 7 to 10 days can be safely administered under careful observation to allow for further time for response.¹² Patients who respond to IV steroid therapy are converted to oral steroids, typically prednisone. Corticosteroids, however, should never be used as a long-term maintenance therapy.^{5,25} The toxic effects of corticosteroids are related to both the dose and duration of treatment. Severe complications, including diabetes, osteoporosis, mood

disturbances, and weight gain, are common with extended use of even modest doses of steroids. Patients should be slowly but completely weaned from steroid therapy. Because recurrence of symptomatic colitis occurs in between 40 and 50% of initial responders to IV therapy, maintenance therapy with either purine analogues, immunosalicylates, or biologics should be administered.^{5,20} Unfortunately, dependency on corticosteroids is often encountered in patients with ulcerative colitis. In these cases, the dose of steroids cannot be tapered without an increase in disease activity and symptoms. When such patients cannot be taken off steroids within 3 to 6 months, then surgical treatment is indicated.

CYCLOSPORINE

Nonresponders to IV steroid treatment, once universally referred for surgery, may be treated with IV cyclosporine. Cyclosporine is an immunosuppressant macrolide that suppresses the production of interleukin-2 by activated T cells through a calcineurin-dependent pathway.²⁶ Originally applied as a means of preventing tissue rejection following transplantation, cyclosporine has become the standard for the treatment of steroid-refractory severe ulcerative colitis. The first report of the use of cyclosporine for the treatment of ulcerative colitis was by Gupta and colleagues in 1984.²⁷ It was not until 10 years later that a randomized placebo-controlled trial of cyclosporine for steroid-refractory ulcerative colitis by Lichtiger and colleagues demonstrated the effectiveness of this agent.²⁸ This revealed a response rate of 82% with 4 mg/kg of cyclosporine in patients with steroid-refractory ulcerative colitis compared to zero response with continued IV steroid therapy alone. Since this initial report, response rates of 56 to 91% have been reported in the medical literature, confirming cyclosporine as a major advance in the treatment of severe and fulminate ulcerative colitis.^{29–31} Dosing and monitoring of cyclosporine are complicated and cumbersome for both physicians and patients, limiting its use. In addition, recurrence of disease after initial remission with cyclosporine is high, with as many as 60% of patients developing recurrent disease.³² Recurrence rates can be substantially lowered with maintenance therapy with mercaptopurine or azathioprine. With appropriate maintenance therapy, early recurrence of symptoms after successful IV cyclosporine treatment have been recorded as low as 22%.^{30,33} Even if disease activity recurs and surgery is necessary, cyclosporine therapy can allow for elective surgical management when the patient is in better general health. This is a clear advantage as urgent surgery for ulcerative colitis carries a much higher risk for complications when compared with surgery performed in a more elective setting.^{18,34,35}

Major side effects associated with cyclosporine treatment include renal insufficiency, opportunistic infections, and seizures. The risk for seizures appears to be highest in patients with hypocholesterolemia. As such, patients with significant (less than 100 mg/dL) hypocholesterolemia should not receive cyclosporine treatment. Hypomagnesemia is commonly seen in patients with fulminant ulcerative colitis undergoing

cyclosporine treatment; hence, serum magnesium levels should be closely followed.

Dosing regimens for cyclosporine vary, but patients are typically started on 4 mg/kg per day of IV cyclosporine, with the dose then adjusted to achieve a whole blood level between 150 and 400 ng/mL as measured by high-performance liquid chromatography or radioimmunoassay.^{36,37} Higher levels up to 800 ng/mL in whole blood have been cited as acceptable by some investigators.²⁸ If the patient does not show any improvement within 4 to 5 days or if complete remission is not achieved by 10 to 14 days, surgery is then advised.¹² Most of the side effects from cyclosporine are dose dependent, and some studies have shown that an initial dose of 2 mg/kg per day of IV cyclosporine can also be effective in achieving a remission.^{38–40}

INFLIXIMAB

Infliximab is a chimeric monoclonal antibody directed against human tumor necrosis factor (TNF). Infliximab has been used to treat Crohn disease for over 10 years. It was not until 2005, however, that infliximab was approved for use in patients with ulcerative colitis. Potential adverse effects from infliximab include activation of tuberculosis, infusion reactions, hypersensitivity reactions, the development of lymphoma, and infectious complications.⁴¹ Additionally, recent accumulating data suggest that infliximab may significantly increase the risk for postoperative infection and healing complications following surgery for ulcerative colitis.^{42,43}

The use of infliximab therapy in the setting of fulminant colitis is controversial. **Whereas the data supporting infliximab in the treatment of moderate to moderately severe disease are convincing, the data demonstrating safety and efficacy in the setting of fulminant colitis are limited. Based on the current data, some experts have supported the initiation of infliximab treatment in patients with fulminant colitis who have failed IV steroid therapy.**⁴⁴ On the other hand, others have advocated the avoidance of infliximab therapy in patients with fulminant colitis.⁴¹ With wider use of anti-TNF therapy for ulcerative colitis, a greater percentage of patients admitted to the hospital with fulminant colitis are likely to already be on infliximab therapy; hence, the decision whether or not to initiate therapy is often moot. Because of the risk of severe complications, infliximab therapy should not be given in combination with cyclosporine therapy.⁴⁵

Because of the increased risk for anastomotic leak and pelvic sepsis in patients undergoing the ileoanal procedure while on anti-TNF therapy, patients with fulminant or severe ulcerative colitis should have a staged abdominal colectomy prior to the ileoanal procedure if they are being treated with infliximab. The negative effect of infliximab on wound healing and infection is prolonged and appears to persist beyond 3 to 4 months after the last dose given.^{42,43}

The prolongation of medical therapy in patients with severe disease who have already received high doses of corticosteroids has caused concerns that those patients who fail both steroid and subsequent cyclosporine or infliximab therapy may be at high risk for perioperative morbidity and mortality. Current experience, however, has not identified an increased risk for perioperative complications in patients who fail to respond to cyclosporine therapy and thus does not appear to compromise surgical results.⁴⁶ Yet recent data on infliximab

in ulcerative colitis do demonstrate a trend toward increased number and severity of septic complications.^{42,43,46}

Surgical Therapy

INDICATIONS FOR SURGERY

The indications for surgery in a patient suffering from fulminant ulcerative colitis are listed in Table 2. When the options for appropriate medical treatment have been exhausted, surgery will, of course, be required. Because most patients suffering from fulminant ulcerative colitis will respond to aggressive medical therapy, an attempt at medical treatment is warranted in almost all cases. Care must be exercised, however, not to overtreat the patient with fulminant ulcerative colitis who is unresponsive or shows minimal response to medical treatment. The immunosuppressive effects of high-dose corticosteroids and IV cyclosporine or infliximab, along with the debilitation of prolonged severe disease, can place the patient at high risk for perioperative complications. **If the patient fails to show significant improvement with IV steroids in 5 to 7 days, then the patient should be started on IV cyclosporine or infliximab or referred for surgery.¹² For patients who fail to show improvement on second-line medications within 4 days or fail to achieve remission of major symptoms by 2 weeks, surgery should be undertaken.** If symptoms progress during the course of IV therapy or if no sign of improvement occurs, then the patient should be considered for early surgery. Additionally, patients known to have deep longitudinal ulcerations may also be referred for early surgery, given that these patients are more likely to fail IV medical therapy. The decision when best to abandon medical therapy in favor of surgery for patients with fulminant ulcerative colitis is difficult and requires experience and special expertise. Thus, patients with fulminant ulcerative colitis are best managed in a center specializing in inflammatory bowel disease.

Patients with perforation or severe bleeding require urgent surgery.⁴⁷ Debilitation from disease and immunosuppression from intensive medical therapy can mask the signs and symptoms of sepsis and peritonitis associated with perforation. When perforation occurs, the risk for perioperative mortality is up to 10 times greater compared to cases of fulminant colitis without perforation.⁴⁸ **For these reasons, patients with high fever, marked leukocytosis, and persistent tachycardia should**

be referred for early surgery, independent of other indications of perforation or peritonitis.

Toxic megacolon is an uncommon complication of severe ulcerative colitis. Associated with impending colonic perforation, toxic megacolon requires aggressive management. Two specific parameters are required to confer the diagnosis of toxic megacolon.⁴⁹ **First, there must be colonic dilatation. Second, the patient should appear “toxic.”** Patients with mild symptoms of ulcerative colitis can experience colonic dilatation, perhaps associated with a colonic ileus. This is distinctly different from patients with fulminant ulcerative colitis, some degree of generalized toxicity, and colonic dilatation. **Patients with fulminant ulcerative colitis should have an abdominal x-ray to assess for colonic dilatation [see Figure 2].** Additionally, patients with fulminant ulcerative colitis who develop abdominal distention or have a sudden decrease in the number of bowel movements without signs of significant clinical improvement should also be assessed radiographically for colonic dilatation.

As noted, patients with toxic megacolon should be treated aggressively. Individuals who are otherwise stable may undergo a brief trial of conservative management consisting of eliminating narcotics and anticholinergic agents. Changing the patient’s position from side to side, supine to prone, and into the knee-elbow prone position is thought to assist in the expulsion of colonic gas.⁵⁰ Patients should be kept NPO, and broad-spectrum IV antibiotics are advocated. Attempts at endoscopic decompression are to be avoided, and blind placement of rectal tubes is ineffective and may be harmful. **Patients with**

toxic megacolon who do not rapidly respond to conservative management and those who show signs of peritonitis are otherwise unstable and should undergo urgent surgery.⁵¹

PREPARATION FOR SURGERY

Patients with fulminant ulcerative colitis who are stable but not responding to medical therapy may have time to prepare for surgery. Patients who are not NPO should be maintained on clear liquids and then kept NPO for 6 to 8 hours prior to surgery. Usually, these patients do not require any form of bowel preparation as they have multiple bloody, liquid bowel movements and will require an emergent colectomy with diversion. If used, bowel preparations may be limited to a rectal washout at the time of surgery. If time allows, patients should be provided with a consultation with an experienced enterostomal therapist and an optimal site for the ostomy should be marked on the abdomen. Prophylactic antibiotics should be given prior to the creation of the surgical incision, and appropriate stress-dose steroids should also be administered.

SURGICAL STRATEGIES

The operative strategies for the treatment of fulminant ulcerative colitis are controversial. Ultimately, almost all patients will end up with a restorative proctocolectomy and an ileoanal anastomosis. Most patients with fulminant ulcerative colitis, however, will have the final surgical goal achieved in multiple steps. The safety of performing an extensive resection with a prolonged and delicate reconstructive procedure in an acutely ill patient is questionable. It has thus been the practice of many to first perform a total abdominal colectomy with an ileostomy, leaving the rectum as a stapled stump or a mucous fistula.^{47,48} This approach allows the patient to recover from the acute illness, to wean off the immunosuppressive agents, and to improve the nutritional status. Although the remaining rectal stump will be affected by ulcerative colitis, the activity of disease is greatly diminished with the fecal diversion, and almost all patients can be completely weaned from steroids and other immunosuppressive medications. A subsequent restorative proctectomy with ileoanal anastomosis can then be performed in a more controlled situation.

The benefits of undergoing a staged procedure may be multiple; some studies have demonstrated a reduced risk of anastomotic leak, but findings are not universal. Ziv and colleagues reported excellent long-term results and acceptable short-term morbidity in 12 patients undergoing immediate restorative proctocolectomy with ileal pouch-anal anastomosis.⁵² The authors used a liberal definition for fulminant colitis that included patients who may not have been as acutely ill and represent an extraordinarily small proportion of the total number of ileoanal procedures performed at their institution. Harms and colleagues reported on 20 patients undergoing restorative proctocolectomy with ileal pouch-anal anastomosis for the urgent treatment of ulcerative colitis and also reported excellent long-term results and exceptional perioperative morbidity.⁵³ However, Heyvaert and colleagues

reported on 12 patients also undergoing urgent restorative proctocolectomy with ileoanal procedure for ulcerative colitis and noted a 41% anastomotic leak rate compared to an 11% leak rate in patients undergoing ileoanal anastomosis under more controlled conditions.⁵⁴ Based on these results, Heyvaert and colleagues counseled against ileoanal anastomosis in the urgent setting. Fukushima and colleagues also noted a higher risk for anastomotic leak (36%) in patients undergoing urgent restorative proctocolectomy with ileoanal anastomosis.⁵⁵ This group likewise advised against performing an ileoanal anastomosis in the urgent setting.

Precise parameters under which it is best to stage the procedure with an initial abdominal colectomy have not been clearly defined. It is universally accepted that patients with perforation, peritonitis, or sepsis require a staged procedure. Any patient with suspicion of Crohn colitis or indeterminate colitis should undergo subtotal colectomy to allow for further diagnostic evaluation prior to creation of ileal pouch-anal anastomosis. Beyond this, there is no clear consensus. The available studies addressing this issue unfortunately involve a small number of patients, do not clearly define what is meant by “fulminant” colitis, or do not directly compare results between the two alternative strategies of staged colectomy versus immediate ileoanal anastomosis. Clearly, there is a small subset of patients with symptoms severe enough to require hospitalization who are healthy enough to safely undergo a primary ileoanal anastomosis. On the other end of the spectrum, severely ill patients, that is, most patients with fulminant colitis, should have a staged procedure. Because specific criteria to quantify the risk have not been defined, the decision to stage or not to stage ultimately rests with the clinical judgment of the experienced surgeon. It has been the author’s experience, however, that a large majority of patients who fit the criteria of fulminant colitis as noted in Table 1 and have failed maximal medical therapy are best managed with a staged approach.

If the procedure is staged and the proctectomy delayed, there are several advantages to the patient in terms of having time to fully consider lifestyle and reproductive options. Living with an ileostomy for 2 to 4 months ensures that the patient understands the relationship between the timing and quality of oral intake and the frequency and consistency of ileostomy output. This knowledge is extremely helpful to the patient in affecting the frequency, timing, and consistency of bowel movements after completion of all stages associated with a restorative proctectomy and ileoanal pouch procedure. Further, it gives the patient confidence that life with an ileostomy is manageable, a notion that may be important if complications of an ileoanal procedure escalate to the point of considering reversal.

All patients who undergo proctectomy face the risk of decreased fertility and sexual function postoperatively, and consideration of timing of surgery is appropriate. If the rectum is acutely inflamed, dissection may be more difficult and injuries to pelvic nerves and formation of adhesions and abscesses may be greater. As a large percentage of the population with ulcerative colitis are in their reproductive prime, preoperative consideration of issues is appropriate.

In males, erectile dysfunction appears to be altered after damage to the parasympathetic nerves, whereas ejaculatory dysfunction results from sympathetic nerve injury. It is estimated that between 0 and 10% of males experience some

degree of sexual dysfunction postoperatively.^{56,57} Although studies demonstrate that dysfunction may be transient and relieved with pharmaceutical agents such as sildenafil, this is a significant consideration for males in the peak of their reproductive years.⁵⁸ Subtotal colectomy has not been associated with decreased function; therefore, males in need of an urgent procedure may defer the proctectomy to a later time and consider cryopreservation prior to the removal of the rectum.

In women, causes of sexual dysfunction are more difficult to determine, but infertility rates are significantly elevated following proctocolectomy. Fecundity rates, or the percentage of women who become pregnant per unit time, are reduced to one third of baseline populations after proctectomy for ulcerative colitis.^{59,60} Adhesions and occlusion of fallopian tubes have been noted in a large number of postoperative patients obstructing normal ovulation and fertilization.^{61,62} Although it would be simple to blame surgery alone, patients requiring ileal pouch-anal anastomosis for familial adenomatous polyposis do not experience this radical decrease in fertility postoperatively.⁶³ Although in vitro fertilization has been highly successful in this group, consideration of postponement of proctectomy for family planning may be reasonable in these patients.⁶⁴

SURGICAL TECHNIQUE

Surgical exploration can be performed with a midline or transverse incision. The abdomen should be carefully examined with particular attention given to the small intestine looking for signs of Crohn disease. The colon often shows the changes of colitis with serosal hyperemia, corkscrew vessels, and edema [see Figure 3]. Colectomy can be performed in the standard fashion with mesenteric division occurring at a convenient distance from the bowel. Wide mesenteric resection is not necessary.

If a staged colectomy is performed, an ileostomy is created in the standard fashion at the site selected as least inconvenient for the patient preoperatively, and the rectum is left behind either stapled or brought up to the abdominal wall as a mucous fistula. When stapled, it is important that the stump be of the appropriate length. Too short of a pouch can lead

to a very difficult proctectomy at the next stage of the procedure sequence. Too long of a stump can run the risk of complications related to persistent disease in the rectum, including bleeding, discharge, and tenesmus. In most cases, the rectum can be safely stapled at the level of the sacral promontory [see Figure 4]. When performing the colectomy, the sigmoid branches of the inferior mesenteric artery are divided, whereas the terminal branches of the inferior mesenteric artery are preserved. This will ensure a good blood supply to the remaining rectal stump and aid in the healing of the stapled closure. Preservation of the terminal branches of the inferior mesenteric artery and the superior rectal artery also simplifies the subsequent proctectomy by keeping the pelvic sympathetic nerves free of surrounding scar tissue and by providing a key anatomic landmark that will assist in the location of the appropriate presacral dissection plane at the time of the proctectomy. To staple the proximal rectum safely, the mesenteric and pericolic fat are removed from the bowel wall. Approximately 2 cm of bowel is prepared in such a manner, and the bowel is then closed with a transverse anastomosis stapler (TIA stapler) using 4.8 mm staples. The bowel is then divided proximal to the staple line. It is important to closely examine the staple line to ensure that the staples are formed properly into two rows of well-formed “B’s.” The staple line should also be examined to make sure that individual staples are not cutting into the muscularis propria of the bowel. To provide extra assurance against dehiscence, the staple line can be oversewn with interrupted Lembert sutures [see Figure 4]. If used, these sutures should be carefully placed so that the anterior and posterior serosal surfaces are approximated without undue tension. In a well-constructed rectal pouch, placement of pelvic drains is not necessary and can be harmful as their placement close to the suture line may promote dehiscence.

In some cases, the colon at the level of the sacral promontory will be affected by deep ulcerations and severe inflammation such that the closure of the rectum at this level may be at high risk for dehiscence [see Figure 5]. If the severity of the disease precludes safe closure of the rectal stump, then creation of a mucous fistula should be considered. The mucous fistula does require a longer segment of bowel and thus is

Figure 3 Intraoperative photograph of colon affected by fulminant ulcerative colitis. Changes on the serosal aspect are typically subtle. Serosal hyperemia with small “corkscrew” vessels is present.

Figure 4 Hartmann pouch constructed at the level of the sacral promontory. The transverse anastomosis stapler line is reinforced with interrupted silk Lembert sutures.

Figure 5 Surgical specimen showing severe ulceration and inflammation seen with fulminate ulcerative colitis.

Figure 6 Laparoscopic colectomy for fulminant ulcerative colitis. Mobilization of the splenic flexure.

associated with a greater risk of bleeding from the retained segment. Additionally, a mucous fistula is unsightly and often generates a very foul odor. As a compromise approach, some surgeons have advocated stapling the rectosigmoid and placing the proximal end of the stump through the fascia at the lower edge of the midline incision. The end of the stump is then left buried in the subcutaneous tissue. The benefit of this approach is that should dehiscence of the staple line occur, then sepsis should be limited to the subcutaneous space rather than result in an intra-abdominal or pelvic abscess.

If attempts to fashion a secure rectal closure fail, and the remaining rectal stump is too short to bring out as a mucous fistula, then two options remain: an additional inch or two of proximal rectum can be resected and closure of the rectal stump performed lower, sometimes just below the peritoneal reflection. In this situation, closed suction drains should be placed in the deep pelvis and, if possible, the peritoneum closed over the rectal stump. Such a short rectal stump, however, will make finding it during subsequent completion restorative proctectomy and ileoanal anastomosis more difficult. Alternatively, a large Malecott drain, inserted through the lower abdominal wall, can be placed in the proximal rectum and the opening of the rectum can be synched around it with a purse-string suture. In this case, as well as in any case where the closure of the rectal stump seems precarious, transanal placement of a rectal tube to drain rectal secretions and blood may be beneficial in reducing the risk of intra-abdominal spillage of rectal contents or of dehiscence of the stapled rectal stump.

LAPAROSCOPY

Experience with laparoscopic-assisted approaches has demonstrated that abdominal colectomy can be performed safely in patients suffering from ulcerative colitis using these minimally invasive approaches.⁶⁵⁻⁶⁷ Mobilization of the colon and

division of the mesentery can be accomplished laparoscopically with the specimen being removed through a small Pfannenstiel incision [see Figure 6]. An end ileostomy is also fashioned with the aid of inspection through the Pfannenstiel incision. Alternatively, the Pfannenstiel incision can be made early on in the procedure and used as a hand assist port and the colon removed using a hand-assisted laparoscopic approach. The clinical advantages of a laparoscopic-assisted approach in the management of fulminate ulcerative colitis have not been fully defined. However, increasing experience with this approach indicates that laparoscopic-assisted colectomy is a safe and reasonable alternative that may well result in shorter hospital stays, decreased postoperative pain, decreased complication rates, and possible reduced adhesions.^{68,69} The laparoscopic-assisted approach thus appears to be a reasonable option for most patients suffering from fulminant ulcerative colitis.

Patients suffering from toxic megacolon, however, should be managed with an open surgical approach as the laparoscopic instruments used to grasp the bowel are likely to cause perforation in the severely thinned walls of the dilated colon.

Summary

The optimal management of fulminate ulcerative colitis is challenging. Most patients will respond to medical therapy such that long-term control of disease can be achieved or at least surgery can be undertaken at later, safer, elective conditions. Surgical strategies must be tailored to account for each individual patient's overall physical condition, with most patients who fail medical therapy requiring an abdominal colectomy as the first step in a staged surgical approach.

14 HEREDITARY COLORECTAL CANCER AND POLYPOSIS SYNDROMES

José G. Guillem, M.D., M.P.H., F.A.C.S., and Harvey G. Moore, M.D.

The majority of cases of inherited colorectal cancer (CRC) are accounted for by two syndromes: hereditary nonpolyposis colorectal cancer (HNPCC) and familial adenomatous polyposis (FAP). In both, the predisposition to disease is a germline mutation transmitted in an autosomal dominant fashion. Although the two syndromes are similar in some respects, differences in their phenotypic expression and in the certainty of disease development mandate distinctly different surgical approaches, including the timing and extent of prophylactic procedures in carefully selected patients. In the management of FAP, the role of prophylactic surgery is clearly defined, though the optimal procedure for an individual patient depends on a number of factors. In the management of HNPCC, the indications for prophylactic procedures are emerging, particularly for unaffected mutation-positive patients.

Two less common polyposis syndromes, Peutz-Jeghers syndrome (PJS) and juvenile polyposis syndrome (JPS), are also inherited in an autosomal dominant fashion and are associated with a significant risk of CRC. Carefully selected persons affected by these syndromes may also benefit from prophylactic surgical procedures. Current evidence supports a role for prophylactic colectomy in JPS but not in PJS.

Finally, there are a few other, less common, inherited hamartomatous polyposis syndromes, such as Cowden disease and Ruvalcaba-Myhre-Smith syndrome. At present, these syndromes appear to be associated with an exceedingly low risk of CRC; accordingly, prophylactic surgery is not indicated.¹

Familial Adenomatous Polyposis

FAP is caused by mutations in the tumor suppressor gene *APC*, located at 5q21. Nearly 80% of FAP patients belong to known FAP kindreds; 10% to 30% have new mutations.¹ More than 300 distinct mutations have been identified within the *APC* gene locus in persons manifesting the FAP phenotype. More than half of the known germline mutations associated with the classic FAP phenotype are concentrated in the 5' region of exon 15.¹ Genotype-phenotype correlative studies have revealed a wide range of phenotypic heterogeneity, ranging from the relatively mild presentation associated with attenuated FAP, which is caused by mutations in the 3' and 5' ends of the *APC* gene,² to the severe presentation associated with mutations downstream from codon 1250, particularly those in codon 1309. It has been reported that as many as 7.5% of patients with a classic FAP phenotype and no demonstrable *APC* mutation may have biallelic germline mutations in the base excision repair gene *MYH*.³

CLINICAL EVALUATION

FAP, which accounts for less than 1% of the annual CRC burden, is characterized by the presence of more than 100 adenomatous polyps of the colorectum, virtually 100% penetrance, and a nearly 100% risk of CRC by the age of 40 if prophylactic colectomy is not performed.^{1,4} Extracolonic manifestations are common and include desmoid tumors, osteomas,

odontomas, sebaceous and epidermoid cysts, congenital hypertrophy of the retinal pigment epithelium, and periampullary neoplasms.¹

INVESTIGATIVE STUDIES

Pathologic Findings

The polyps, which develop by the age of 20 years in 75% of cases, are typically less than 1 cm in size. In severe FAP, they may carpet the entire surface of the colorectal epithelium or, alternatively, may spare portions of the epithelial lining (e.g., the rectum). Adenomas may be either pedunculated or sessile and may have tubular, villous, or tubulovillous histology. Microscopic evaluation may reveal innumerable microadenomas within grossly normal-appearing colorectal mucosa. Foci of carcinoma in situ and invasive carcinoma may be found within larger polyps, and the incidence of invasive cancer is proportional to the extent of polyposis. Unlike CRC in the setting of HNPCC, CRC in the setting of FAP is more commonly located on the left side.¹

Screening and Surveillance

Screening (genetic testing or annual or biennial flexible sigmoidoscopy) for at-risk family members should begin around puberty (i.e., at 10 to 12 years of age) [see Table 1]. In families with a demonstrated *APC* mutation, informative genetic testing can be carried out with the protein truncation test [see Table 2]. This test, which detects foreshortened proteins resulting from truncating *APC* mutations, is approximately 80% sensitive⁵; however, the test results are commonly misinterpreted, even by physicians.⁶ Patients with normal protein truncation test results and a previously identified mutation in the family may be discharged from further screening with a nearly 100% certainty that the mutation is absent, but they should still undergo CRC screening starting at the age of 50 years, as is recommended for average-risk persons. When an *APC* mutation has not previously been identified in the family of an affected person, the patient should be tested first to identify the causative mutation. In families in which the protein truncation test fails to provide conclusive information on carrier status, at-risk individuals should continue with the recommended endoscopic surveillance program. Other options for detecting *APC* mutations include linkage analysis, single-stranded confirmation polymorphism, and direct sequence analysis.¹

Genetic counseling is an essential component of the evaluation of patients for FAP. Patients who have a positive genotype or who have adenomatous polyps on sigmoidoscopy should undergo full colonoscopy to establish the extent of polyposis.

MANAGEMENT

Medical Therapy

A number of nonsteroidal anti-inflammatory drugs, including sulindac, celecoxib, and the sulindac metabolite exisulind, have been shown to reduce the number and size of polyps in FAP

Table 1 Genetic Basis, Clinicopathologic Features, Diagnosis, Surveillance, and Surgical Management of Hereditary CRC and Polyposis Syndromes

Syndrome	Genetic Basis	Diagnosis	GI Manifestations	Extracolonic Manifestations	Pathologic Features	CRC Screening and Surveillance	Surgical Management
FAP	APC, 5q21 (> 90%); MYH (8%)	≥ 100 adenomatous polyps of colorectum or APC mutation demonstrated	Adenomatous polyps of colon and rectum 100% risk of colorectal cancer by age 40 without colectomy	Desmoids Osteomas Odontomas Sebaceous and epidermoid cysts CHRPE Periampullary neoplasms	Tubular, villous, or tubulovillous histology	Consider genetic counseling/testing Carry out early surveillance with sigmoidoscopy (at age 10–12 yr) ^{98,99} For at-risk untested individuals, perform FS every 1–2 yr	If polyposis is confirmed, colectomy is indicated Options include the following: TPC with ileostomy TAC with IRA TPC with IPAA
HNPCC	MMR genes: MLH1 and MSH2 (90%), MSH6 (10%), PMS1, PMS2, MLH3, MSH3	MMR mutation demonstrated or Family meets Amsterdam I or II criteria ^{50,51}	Possibly few or no colorectal polyps Right-side tumor (60%–70%) MSI-high tumor (80%–90%) Synchronous/metachronous tumors 80% lifetime risk of CRC	Associated tumors of endometrium, small bowel, ureter, or renal pelvis	Adenocarcinoma, frequently mucinous or signet-ring cell histology Solid or cribriform growth pattern Tumor-infiltrating or peritumoral lymphocytes	Consider genetic counseling/testing If patient is mutation positive or is untested but meets criteria, perform colonoscopy at 20–25 yr (or 10 yr earlier than youngest affected individual), then every 1–2 yr, then annually after age 40 ^{98,99}	<i>Affected patient with identified mutation or meeting Amsterdam criteria:</i> Colon cancer or advanced adenoma: perform TAC with IRA or segmental colectomy with annual colonoscopy Rectal cancer: perform TPC with IPAA or LAR and annual colonoscopy <i>Unaffected patient with identified mutation or meeting Amsterdam criteria:</i> Consider TAC with IRA or colonoscopy every 1–3 yr
PJS	LKB1/STK11, 19p13.3 (18%–63%)	Hamartomas of GI tract and At least two of the following: Small bowel disease Mucocutaneous melanin Family history of PJS	Hamartomatous polyps throughout entire GI tract (small intestine, 90%; colon, 50%) Relative risk of CRC = 84	Mucocutaneous pigmentation (perioral and buccal areas, 95%)	Hyperplasia of smooth muscle of muscularis mucosa Arborization Pseudoinvasion	Consider genetic counseling/testing Perform colonoscopy starting between puberty and age 25, then every 2–3 yr ⁸⁸	Perform operative or laparoscopy-assisted polypectomy or segmental colectomy for polyps > 1.5 cm that are not amenable to endoscopic resection Perform segmental bowel resection for invasive cancers In the setting of laparotomy, perform intraoperative endoscopy (peroral or via enterotomy) <i>Prophylactic colectomy has no role⁸⁸</i>
JPS	SMAD4/DPC4, 18q21.1 (50%); BMPR1A, 10q22.3	≥ 3 juvenile polyps of colon and juvenile polyps throughout GI tract or Any number of polyps with family history of JPS	Multiple hamartomatous polyps throughout gastroduodenum 15% risk of CRC by age 35, 68% risk by age 65	Tumors of stomach, pancreas, duodenum	50–200 polyps Cystic, mucus-filled spaces with epithelial lining Attenuated smooth muscle layer Focal epithelial hyperplasia and dysplasia	Consider genetic counseling/testing Perform colonoscopy in middle to late teenage years, with EGD and SBS; if results are negative, repeat in 3 yr, then every 3 yr if results remain negative; if results are positive, perform biopsy of polyps and intestinal mucosa	<i>Disease is local, and no significant symptoms are present:</i> Manage endoscopically, with colonoscopic surveillance every 1–3 yr <i>Disease is diffuse or significant symptoms are present:</i> Perform TAC with IRA, and carry out rectal surveillance every 1–3 yr

CHRPE—congenital hypertrophy of retinal pigment epithelium CRC—colorectal cancer EGD—esophagogastroduodenoscopy FAP—familial adenomatous polyposis FS—flexible sigmoidoscopy HNPCC—hereditary nonpolyposis colorectal cancer IPAA—ileal pouch–anal anastomosis IRA—ileorectal anastomosis JPS—juvenile polyposis syndrome LAR—low anterior resection MMR—mismatch repair MSI—microsatellite instability PJS—Peutz-Jeghers syndrome SBS—small bowel series TAC—total abdominal colectomy TPC—total proctocolectomy

patients.^{7–10} However, long-term use of chemopreventive agents for primary treatment of FAP is not recommended.¹¹ In a randomized, placebo-controlled, double-blind study of genotype-positive, phenotype-negative patients, the use of sulindac had no effect on the subsequent development of colorectal polyposis.¹² Furthermore, the development of rectal cancer has been reported in patients whose rectal polyps were effectively controlled with sulindac.¹⁰ Finally, these medications necessitate continued com-

pliance⁹ and may be associated with significant side effects. Chemopreventive agents may be useful for reducing polyp load and facilitating endoscopic management of polyps in patients who have an ileal pouch or in patients who have an ileorectal anastomosis, are at high risk for polyp development, and refuse proctectomy. In such cases, however, it is still necessary to perform careful surveillance of the residual rectum or the ileoanal pouch every 6 months.¹¹

Surgical Therapy

The timing of surgical treatment depends to some degree on the extent of polyposis, in that the risk of CRC is partially dependent on the number of polyps present.¹³ Patients with mild polyposis (and thus a lower cancer risk) can undergo surgery in their midteens.¹¹ Practically speaking, the best time is usually the summer between high school and college. Patients with severe polyposis, dysplasia, adenomas larger than 5 mm, and significant symptoms should undergo surgery as soon after diagnosis as is practical.¹¹

There are three basic surgical options for treating FAP: (1) total proctocolectomy (TPC) with permanent ileostomy, (2) total abdominal colectomy with ileorectal anastomosis (IRA), and (3) proctocolectomy with ileal pouch–anal anastomosis (IPAA) [see 5:33 *Procedures for Ulcerative Colitis*]. The optimal procedure for a given patient is determined on the basis of a number of factors, including disease characteristics, differences in postoperative functional outcome, preoperative anal sphincter status, and patient preference.

TPC TPC with permanent ileostomy is rarely chosen as a primary procedure. More commonly, it is considered as an option for patients in whom a proctectomy is required but an IPAA is contraindicated (e.g., those with rectal tumors involving the sphincters or the levator complex or those with poor baseline sphincter function) or for patients in whom an IPAA is not technically feasible (e.g., those with desmoid disease and foreshortening of the small bowel mesentery). Occasionally, however, TPC is chosen as a primary procedure in patients whose lifestyle would be compromised by frequent bowel movements.

IPAA versus IRA The choice between IPAA and IRA is generally more challenging. The main considerations to be taken

into account are the risk of rectal cancer development if the rectum is left in situ and the differences in functional outcome (and associated quality of life) between procedures.

It has been estimated that the risk of rectal cancer after IRA may be as high as 4% to 8% at 10 years and 26% to 32% at 25 years.^{14,15} The true risk, however, may be somewhat lower. Most of the studies from which these figures were derived were completed before IPAA became available; thus, patients and physicians might have been more likely to choose IRA even in the setting of more extensive rectal disease, given that TPC and permanent ileostomy was the only other option at the time. The magnitude of risk in an individual patient is related to the overall extent of colorectal polyposis. IRA may be an option for patients with fewer than 1,000 colorectal polyps (including those with attenuated FAP) and fewer than 20 rectal adenomas, because these patients appear to be at relatively low risk for rectal cancer.^{11,13,16} Ideally, patients with severe rectal (> 20 adenomas) or colonic (> 1,000 adenomas) polyposis, an adenoma larger than 3 cm, or an adenoma with severe dysplasia should be treated with IPAA.^{11,13}

The risk of secondary rectal excision as a consequence of uncontrollable rectal polyposis or rectal cancer may be estimated on the basis of the specific location of the causative *APC* mutation.¹⁵⁻¹⁷ In a study of 87 FAP patients with an identified *APC* mutation who underwent IRA, those with a mutation located downstream from codon 1250 had an approximately threefold higher incidence of secondary rectal resection than those with a mutation located upstream of codon 1250.¹⁴ Furthermore, patients with a mutation located between codons 1250 and 1464 had a 6.2-fold higher risk of rectal cancer than those with a mutation before codon 1250 or after codon 1464.¹⁵

The risk of polyp and cancer development after index surgery is not limited to patients undergoing IRA. In patients undergoing IPAA, the pouch–anal anastomosis may be either handsewn after

Table 2 Availability of Commercial Genetic Testing for Autosomal Dominant Inherited CRC Syndromes

Test	Approximate Time Frame	Approximate Cost	Clinical Availability (in United States)
Protein truncation test	4–6 wk	\$1,100; if mutation known, \$475	Mayo Clinic, Rochester, Minn.; (800) 533-1710 Washington University, St. Louis, Mo.; (314) 454-7601

complete anal mucosectomy or stapled to a 1 to 2 cm anal transition zone. Neoplasia may occur at the site of the anastomosis, and the incidence appears to be higher after stapled anastomosis (28% to 31%) than after mucosectomy and handsewn anastomosis (10% to 14%).^{18,19} Function, however, may be better after stapled anastomosis.¹⁹ In the case of anal transition zone neoplasia after stapled anastomosis, transanal mucosectomy can often be performed, followed by advancement of the pouch to the dentate line. Of additional concern is the development of adenomatous polyps in the ileal pouch itself, which occurs in 35% to 42% of patients at 7 to 10 years.²⁰⁻²²

With respect to postoperative bowel function and associated quality of life, IPAA has been associated with a higher frequency of both daytime and nocturnal bowel movements, a higher incidence of passive incontinence and incidental soiling, and higher postoperative morbidity than IRA.²³ Accordingly, some authors recommend IRA for patients with mild rectal polyposis. Other authors, however, have found the two approaches to be equivalent in terms of functional results²⁴ and quality of life²⁵ and therefore recommend IPAA for most patients because of the risk of rectal cancer associated with IRA.

Regardless of which procedure is performed, however, lifetime surveillance of the rectal remnant (after IRA) or the ileal pouch (after IPAA) is required.¹¹ Endoscopic surveillance of the bowel at intervals of 6 months to 1 year after index surgery is recommended.^{5,11} After IRA, small (< 5 mm) adenomas may be safely observed, with biopsy performed to rule out severe dysplasia. If adenomas increase in number, the frequency of surveillance should be increased, and polyps larger than 5 mm should be removed. When fulguration and polypectomy are repeated over a period of many years, subsequent polypectomy may become difficult, rectal compliance may be reduced, and flat cancers may be hard to identify against a background of scar tissue. The development of severe dysplasia or a villous adenoma larger than 1 cm is an indication for proctectomy.¹¹

Extracolonic Disease

After total abdominal colectomy with IRA and regular surveillance, the risk of death appears to be three times higher for FAP patients than for an age- and sex-matched control population.²⁶ The main causes of death after IRA are desmoid disease and upper gastrointestinal malignancy.

Desmoid disease Desmoids are histologically benign tumors that arise from fibroaponeurotic tissue and occur in 12% to 17% of FAP patients.^{11,27,28} Unlike those in the general population, desmoids in FAP patients tend to be intra-abdominal (up to 80% of cases) and mainly occur after abdominal surgical procedures.^{27,28} Patients with *APC* mutations located between codons 1310 and 2011 are at increased risk for these tumors.²⁹ Desmoids often involve the small bowel mesentery (> 50% of cases),²⁸ making complete resection difficult or impossible, and they may also involve the ureters.²⁷ Not uncommonly, patients present with small bowel obstruction.^{27,28} Morbidity after attempted resection, which often involves removal of a significant length of small bowel, is substantial. The recurrence rate after attempted resection is also high, and the recurrent disease is often more aggressive than the initial desmoid.^{27,28}

Intra-abdominal desmoid formation may be more common after IRA than after IPAA, and the disease may be more severe after IRA as well.^{28,30} When desmoid tumors involve the small bowel mesentery, the mesentery may become foreshortened and thereby render IPAA impracticable, especially in patients under-

going a subsequent completion proctectomy after an initial IRA.¹¹ This possibility should be considered in making the choice between IRA and IPAA as the initial procedure for FAP.

Medical therapy. When desmoid tumors are clinically inert, they may be treated with sulindac.¹¹ Tamoxifen or other antiestrogens may be added for slow-growing or mildly symptomatic tumors.^{11,31,32} More aggressive desmoid tumors may be treated with chemotherapy. Vinblastin and methotrexate achieve some degree of response in 40% to 50% of patients.³³ For more rapidly growing desmoids, antineoplastic agents, such as doxorubicin and dacarbazine, may be administered.^{34,35} Radiation therapy may also be effective, but it can result in substantial small bowel morbidity.

Surgical therapy. Surgical treatment of intra-abdominal desmoid tumors should be reserved for small, well-defined lesions with clear margins.¹¹ When intra-abdominal desmoids involve the small bowel mesentery, they should be treated according to their initial presentation and rate of growth. In patients with desmoid lesions that are refractory to all medical treatment and call for surgical treatment with extensive small bowel resection, small bowel transplantation may be feasible in selected cases.³⁶

Periampullary neoplasms In approximately 80% to 90% of persons with FAP, duodenal adenomas, periampullary adenomas, or both will develop.³⁷ Of these patients, 14% to 50% will eventually exhibit advanced polyposis, and as many as 6% will eventually have invasive cancer.^{1,38-42} Although the risk of periampullary or duodenal cancer in FAP patients is relatively low, it is still several hundred times higher than that in the general population. Among FAP patients, those with *APC* mutations between codons 976 and 1067 appear to have the highest incidence of duodenal adenoma.

Surveillance should begin with side-viewing esophagogastroduodenoscopy (EGD) and biopsy of suspicious polyps either at the age of 20 years or at the time of prophylactic colectomy, whichever is earlier.¹¹ The purpose of screening is not to remove all disease but to watch for the development of high-grade dysplasia. Small, tubular adenomas without high-grade dysplasia may be biopsied and observed; adenomas that are larger than 1 cm or that exhibit high-grade dysplasia, villous changes, or ulceration should be removed. Surgical options include endoscopic removal and transduodenal excision, but both approaches have drawbacks: endoscopic ablation generally requires multiple settings,³⁸ and recurrence is high after either procedure.^{38,43} Endoscopic ablation is a reasonable initial approach for most patients without invasive cancer and is an attractive alternative for patients who are unfit for duodenal resection. For patients with persistent or recurrent high-grade dysplasia in the papilla or duodenal adenomas and for patients with Spigelman stage IV disease, pancreas-preserving duodenectomy or pancreaticoduodenectomy is recommended.¹¹ The results reported for duodenal resection in patients with premalignant lesions are encouraging, with good local control and low morbidity.^{38,44,45} Duodenectomy also greatly reduces the need for upper GI surveillance.

Hereditary Nonpolyposis Colorectal Cancer

HNPCC, which accounts for 5% to 7% of CRCs, results from a mutation in one of the DNA mismatch repair (MMR) genes (*MLH1*, *MSH2*, *MSH6*, *PMS1*, *PMS2*, *MLH3*, and *MSH3*).^{46,47} Two genes (*MLH1*, *MSH2*) may be responsible for as many as 90% of causative germline MMR mutations. However, only 50%

to 70% of patients meeting clinical criteria for HNPCC have an identifiable germline MMR mutation, which suggests that one or more unidentified genes may be involved. A significant percentage of cases may be attributable to large germline deletions that are difficult to detect by means of direct sequencing. It appears that genomic deletions may account for as many as 7% of HNPCC cases defined on the basis of clinical criteria.⁴⁸

CLINICAL EVALUATION

HNPCC is characterized by early-onset CRC, a predominance of lesions proximal to the splenic flexure (60% to 70% of cases), benign and malignant extracolonic tumors, and a predilection for synchronous and metachronous colorectal tumors.⁴ Microsatellite instability (MSI), reflecting a deficiency in DNA repair secondary to a mutation in the MMR genes, is noted in approximately 80% to 90% of HNPCC-related tumors.⁴ The lifetime risk of CRC in HNPCC patients is approximately 80%.^{11,49}

Establishing a clinical diagnosis of HNPCC is much more challenging than establishing a clinical diagnosis of FAP, in that it requires a careful and detailed family history. The Amsterdam II criteria [see Table 3] require that there be three relatives (of which one must be a first-degree relative of the other two) with an HNPCC-related cancer (of the colorectum, the endometrium, the small bowel, the ureter, or the renal pelvis), that two or more successive generations be involved, and that at least one relative have a CRC diagnosed before the age of 50.^{50,51} Finally, FAP should be excluded. CRC occurs in 78% to 80% of MMR mutation-positive patients at a mean age of 46 years.^{1,49,52} Endometrial cancer occurs in 43%, gastric cancer in 19%, urinary tract cancer in 18%, and ovarian cancer in 9%.⁵³

INVESTIGATIVE STUDIES

Pathologic Findings

Adenomas in HNPCC patients show high-grade dysplasia and villous changes more frequently than adenomas in sporadic CRC patients.¹ Adenomas may also appear at an earlier age and are often larger than those found in the general population. Other pathologic features reported to be more common in HNPCC-related cancers include a mucinous or poorly differentiated histology, a solid or cribriform growth pattern, signet-ring cell tumors, and the presence of tumor-infiltrating and peritumoral lymphocytes. HNPCC-related CRCs have also been shown to have a lower rate of lymph node involvement.⁵⁴

Screening and Surveillance

CRC patients who belong to known HNPCC kindreds, who have a pedigree suggestive of HNPCC, or who meet the Bethesda criteria [see Table 4]⁵⁵ should be offered screening by MSI testing. MSI evaluation will yield positive results (i.e., an MSI-high tumor) in 80% to 90% of patients belonging to families that meet the Amsterdam criteria. Patients with MSI-high tumors should undergo testing for germline MMR mutations (tests for *MSH2* and *MLH1* are available commercially [see Table 2]). If tumor tissue is not available, initial germline testing may be considered. As in FAP, a mutation in an affected individual must first be established for testing in at-risk individuals to be informative.⁵

Recommended surveillance for HNPCC includes colonoscopy, initially every 1 to 2 years beginning at the age of 20 to 25, then annually after the age of 40.⁵⁶ Given the increasing evidence of an accelerated adenoma-carcinoma sequence in HNPCC, annual colonoscopy should be strongly considered.⁴ Female patients should undergo annual transvaginal ultrasonography and mea-

Table 3 Clinical Criteria for Diagnosis of HNPCC

Amsterdam criteria I ⁵⁰	Three or more relatives with CRC One first-degree relative of the other two One CRC diagnosed at age < 50 yr Two or more successive generations FAP excluded
Amsterdam criteria II ⁵¹	Three or more relatives with an HNPCC-associated cancer (in colorectum, endometrium, small bowel, ureter, or renal pelvis) One first-degree relative of the other two Two or more successive generations One CRC diagnosed at age < 50 yr FAP excluded

surement of CA125 levels starting at 25 to 35 years of age, as well as annual endometrial aspiration.⁵⁶ Annual EGD is recommended for patients belonging to kindreds with a history of gastric cancer. Finally, ultrasonography and urine cytology every 1 to 2 years may be considered to screen for urinary tract malignancy.

MANAGEMENT

Surgical Therapy

Although the development of CRC in persons with HNPCC is not a certainty, the 80% lifetime risk,¹ the 45% rate of metachronous tumors, and the possibility of an accelerated adenoma-carcinoma sequence⁴ mandate consideration of prophylactic surgical options. Patients who have HNPCC as defined by their genotype or the Amsterdam criteria [see Table 3] and who have a colon cancer or more than one advanced adenoma should be offered either (1) prophylactic total abdominal colectomy with IRA or (2) segmental colectomy with yearly colonoscopy [see 5:34 Segmental Colon Resection].^{11,57,58} (The first option, however, is open only to patients with normal rectal and anal sphincter function.) Although the risk of metachronous colon cancers may be higher after partial colectomy than after total colectomy with IRA, intensive colonoscopic surveillance and polypectomy may minimize the number of metachronous cancers in the remaining colon.^{52,59} Careful surveillance is also necessary after total colectomy and IRA, given that the risk of metachronous rectal cancer after total colectomy is approximately 12% at 10 to 12 years.⁶⁰

HNPCC patients with an index rectal cancer that is amenable to a sphincter-preserving resection should be offered either (1) total proctocolectomy with IPAA [see 5:33 Procedures for Ulcerative Colitis] or (2) low anterior resection (LAR) with primary reconstruction [see 5:35 Procedures for Rectal Cancer].^{11,58} The rationale

Table 4 Revised Bethesda Guidelines for Testing CRC Patients for MSI⁵⁵

CRC diagnosed at age < 50 yr
Presence of synchronous or metachronous CRC or other HNPCC tumors (regardless of age)
CRC with HNPCC-like histology at age < 60 yr
CRC in one or more FDR with an HNPCC-related tumor (one diagnosed at age < 50 yr)
CRC in two or more first- or second-degree relatives with HNPCC-related tumors (regardless of age)

FDR—first-degree relative

for total proctocolectomy is based on the 17% to 45% rate of metachronous cancer in the remaining colon associated with an index rectal cancer in HNPCC patients.⁶¹ The decision between the two procedures depends in part on the patient's willingness to undergo intensive surveillance of the retained proximal colon, as well as on the level of bowel function.

Mutation-positive patients with a normal colorectum may also be offered prophylactic colectomy in selected cases.^{56,62} This approach is supported by the similarity of lifetime cancer risk between patients with germline *APC* mutations and those with MMR mutations, as well as by the observation that total abdominal colectomy with IRA yields less functional disturbance than the prophylactic procedure recommended for FAP (total proctocolectomy with IPAA).^{56,62} An alternative strategy in these patients is to carry out colonoscopic surveillance at 1- to 3-year intervals. This strategy has proved to be cost-effective⁶³ and to reduce both the rate of CRC development and overall mortality.^{52,64,65} There is a risk that CRC may develop in the intervals between colonoscopies^{64,66}; however, when the surveillance interval is shorter than 2 years, tumors tend to be found in their early stages and to be curable when found.^{52,64}

A study using a decision-analysis model suggested that prophylactic total abdominal colectomy at the age of 25 might offer a survival benefit of 1.8 years when compared with colonoscopic surveillance. The benefit of prophylactic colectomy decreased when surgery was delayed until later in life and became negligible when it was performed at the time of cancer development.⁶⁵ However, surveillance provided a greater benefit with respect to quality of life (measured in quality-adjusted life years).⁶⁵ On the basis of this evidence, some surgeons recommend that prophylactic colectomy be performed only in highly selected situations (e.g., when colonoscopic surveillance is not technically possible or when a patient refuses to undergo regular surveillance). Thus, the decision between prophylactic surgery and surveillance for gene-positive unaffected patients is based on many factors, including the penetrance of disease in a family, the age of cancer onset in family members, functional and quality-of-life considerations, and the likelihood of patient compliance with surveillance.

Extracolonic Disease

Management of extracolonic cancers in HNPCC patients is not yet well defined. Female patients with a family history of uterine cancer should be offered prophylactic total abdominal hysterectomy (TAH) if their childbearing is complete or if they are undergoing abdominal surgery for other conditions.¹¹ This recommendation is based on the high (43%) rate of endometrial cancer in mutation-positive persons,⁵³ particularly those with *hMSH2* mutations, and on the inefficacy of screening in some studies.⁶⁷ Oophorectomy should be added to TAH because of the high (9%) incidence of ovarian cancer in HNPCC patients⁵³ and the frequent coexistence of endometrial cancer with ovarian cancer.⁶⁸ The optimal timing for prophylactic TAH is unclear; however, endometrial cancer has been reported in HNPCC patients before the age of 35. At present, it seems reasonable to begin surveillance at the age of 25 and delay prophylactic surgery until childbearing is complete.¹¹

Peutz-Jeghers Syndrome

Like FAP and HNPCC, PJS follows an autosomal dominant pattern of inheritance with variable penetrance. It is caused in part by mutations in the gene *LKB1/STK11*, which maps to the telomeric region of chromosome 19p13.3. This gene, which codes for

a multifunctional serine-threonine kinase, is thought to function as a tumor suppressor gene.⁶⁹⁻⁷² Germline mutations in *LKB1/STK11* can be demonstrated in 18% to 63% of PJS patients, which suggests the existence of additional PJS loci.⁷²⁻⁷⁵ Genetic testing for PJS can be accomplished through direct sequencing of the *LKB1/STK11* gene [see Table 2]; however, such testing is not widely available. In families with an established mutation, genetic testing of at-risk individuals is informative, with a reported accuracy of 95%.⁷⁶

CLINICAL EVALUATION

PJS is a hereditary polyposis syndrome characterized by hamartomas of the GI tract, as well as by mucocutaneous melanin pigmentation. Hamartomatous polyps may occur throughout the GI tract but are most frequently found in the small intestine (90%). Other common sites of hamartomas in PJS are the large intestine (50%) and the stomach; less common sites are the renal pelvis, the bile ducts, the urinary bladder, the lungs, and the nasopharynx.^{1,77,78} Mucocutaneous pigmentation generally appears during infancy. The perioral and buccal areas are involved in 95% of cases; the periorbital and facial areas, the genital region, and the acral areas (including the hands and feet) may be involved as well.¹ The average age of diagnosis of PJS is 22 years in men and 26 years in women.

In as many as 86% of cases, the initial presentation of PJS is small bowel obstruction secondary to intussusception of hamartomas. Other presentations include acute or chronic GI bleeding, biliary and gastric outlet obstruction, and anal protrusion of polyps. The diagnosis of PJS is established by the presence of histologically confirmed hamartomas of the GI tract plus two of the following three criteria: (1) small bowel polyposis, (2) mucocutaneous melanotic pigmentation, and (3) a family history of PJS [see Table 1].⁷⁹

Patients with PJS are at significantly increased risk for both intestinal and extraintestinal malignancies. A meta-analysis found that in comparison with the general population, PJS patients were at a relative risk of 15.2 for the development of any malignancy.⁸⁰ The relative risks for the development of specific cancers were as follows: small bowel, 520; gastric, 213; pancreatic, 132; colorectal, 84; esophageal, 57; ovarian, 27; lung, 17; endometrial, 16; and breast, 15. The cumulative risk for the development of any cancer between the ages of 15 and 64 was 93%.⁸⁰ Other cancers associated with PJS are cholangiocarcinomas, testicular neoplasms, and duodenal tumors.¹

Although the relative risk for the development of CRC was high in this study,⁸⁰ the reported magnitude of risk in the individual studies included in the meta-analysis varied considerably. Previous studies also reported a wide range of CRC incidences in these patients.¹ Thus, the true incidence of CRC in PJS patients remains unclear.

INVESTIGATIVE STUDIES

Pathologic Findings

The polyps seen in PJS are hamartomas characterized by hypertrophy or hyperplasia of the smooth muscle of the muscularis mucosa. Smooth muscle extends into the superficial epithelial layer of the bowel wall in a treelike fashion (a process referred to as arborization). Epithelial cells may become entrapped within the muscle layer, and this "pseudoinvasion" can be mistaken for malignant transformation. Therefore, to diagnose a malignancy in a PJS polyp, cellular atypia or an elevated mitotic rate must be documented.⁸¹ Sporadic PJS polyps do occur, generally secondary

to somatic *LKB1/STK11* mutations in one or both alleles, and are histologically identical to their hereditary counterparts. These sporadic polyps appear not to be associated with an increased risk of GI cancer.⁸²

Histologically, areas of cutaneous pigmentation reveal an increased number of melanocytes at the dermal-epidermal junction, with elevated melanin levels in the basal cells. These lesions do not appear to have any malignant potential.

Screening and Surveillance

Clinical screening of asymptomatic persons is facilitated by the appearance of perioral hyperpigmentation during early childhood. Once the diagnosis of PJS is made, patients generally enter a surveillance program. Recommended surveillance for GI disease includes annual serum hemoglobin measurement and EGD every 2 to 3 years, beginning between the ages of 10 and 25.^{79,83-85} Contrast radiography is employed to examine the remainder of the small bowel, beginning at the age of 10 and repeated every 2 to 3 years.^{79,85} The frequency of surveillance examinations may be modified in individual circumstances. Colonoscopic surveillance is also important, commencing between puberty and the age of 25 and repeated every 2 to 3 years.^{83,85} Sigmoidoscopy should not be employed for surveillance, because the rectum may be spared in some patients with more proximal disease. Organ-specific surveillance for other associated malignancies should also be initiated in accordance with current high-risk recommendations.

MANAGEMENT

Medical Therapy

Cyclooxygenase-2 (COX-2) is known to be overexpressed in the hamartomatous tissue of PJS patients, and there is a correlation between expression of the COX-2 protein and expression of the *LKB1/STK11* protein in PJS polyps and cancers.^{86,87} These findings suggest that COX-2 may be a potential target for chemoprevention of PJS.

Surgical Therapy

Indications for surgical management of PJS include the presence of polyps larger than 1.5 cm that cannot be removed endoscopically, incomplete removal of polyps with adenomatous changes, the development of polyp-associated complications (e.g., obstruction, intussusception, and bleeding), and the management of malignant disease.⁸⁸

Endoscopic polypectomy is generally employed as initial therapy when it is technically feasible. For some polyps, however, operative polypectomy performed through an enterotomy is required. Segmental resection should be avoided. In the context of a laparotomy, intraoperative endoscopy (either peroral or via an enterotomy) allows direct visualization of the remainder of the small bowel and endoscopic clearance of any synchronous polyps. This procedure significantly reduces the need for subsequent laparotomy. The St. Mark's Hospital group in London found that none of 25 patients who underwent enteroscopy during laparotomy required subsequent laparotomy within a 4-year period, whereas 17% of historical control patients who did not undergo intraoperative enteroscopy required repeat laparotomy within a 1-year period.⁸⁹

Laparoscopy-assisted polypectomy and laparoscopic management of small bowel intussusception are additional surgical options.

Given the risk of CRC development in PJS patients, careful colonoscopic surveillance is clearly warranted. However, the role of prophylactic colectomy in patients who are at risk or are mutation

positive is unclear. Because the true risk of CRC in these patients is unknown and genetic testing for PJS is not widely available, no recommendations can be made at present regarding the role of prophylactic colectomy in the PJS population.⁸⁸

Juvenile Polyposis Syndrome

Initial evidence suggested that mutations in the *PTEN* gene were responsible for JPS⁹⁰; however, subsequent evidence implicated *SMAD4/DPC4* at 18q21.1 as a more common cause, accounting for as many as 50% of familial cases.⁹¹⁻⁹³ Mutations in *BMPRI1A* at 10q22-q23 have also been reported to cause JPS but display variable penetrance [see Table 2].^{94,95} Clonal genetic alterations are detected in stromal rather than epithelial cells, which suggests that the genetic changes in juvenile polyps originate in the nonepithelial component of the polyps.

CLINICAL EVALUATION

Like PJS, JPS is characterized by the development of multiple hamartomas throughout the GI tract. Isolated juvenile polyps are common in children and are found in approximately 1% of persons younger than 21 years. Juvenile polyposis, however, is much less common. A family history of juvenile polyposis is present in 20% to 50% of patients.¹ Although JPS is an autosomal dominant disorder, its variable penetrance results in a less obvious pattern of inheritance than is seen with FAP or HNPCC.

JPS affects the two sexes equally and generally manifests itself during the first or second decade of life (mean age at diagnosis, 18.5 years).¹ Common presenting symptoms include chronic anemia, acute GI bleeding, prolapse of rectal polyps, protein-losing enteropathy, and intussusception with or without obstruction.¹

Extracolonic manifestations of JPS include gastroduodenal and small bowel polyps, malrotation of the midgut, and mesenteric lymphangiomas. Extraintestinal manifestations include clubbing, hypertrophic pulmonary osteoarthropathy, hydrocephalus and macrocephaly, alopecia, cleft lip and palate abnormalities, supernumerary teeth, porphyria, congenital cardiac and arteriovenous malformations, psoriasis, vitelointestinal duct abnormalities, renal structural abnormalities, and bifid uterus and vagina. JPS is also part of the phenotype for Ruvalcaba-Myhre-Smith syndrome and Gorlin syndrome. Cowden disease, which is characterized by hamartomatous polyposis and is associated with breast and thyroid cancer, may be a phenotypic variant of JPS.^{1,95}

The diagnostic criteria for JPS are as follows: (1) the presence of three or more juvenile polyps of the colon; (2) the presence of juvenile polyps throughout the entire GI tract; or (3) the presence of any number of polyps in a patient with known family history of JPS [see Table 1].⁸⁵ The clinical presentation of JPS can be divided into three main clinical variants: (1) JPS of infancy, which is a non-sex-linked recessive condition characterized by failure to thrive, susceptibility to infections, protein-losing enteropathy, bleeding, diarrhea, rectal prolapse, intussusception, and death by the age of 2 years in severe cases; (2) generalized JPS, which occurs in the first decade of life and is characterized by juvenile polyps throughout the GI tract; and (3) JPS of the colon, the most common presentation, which is characterized by colonic polyposis only.¹

Patients with JPS appear to be at increased risk for GI malignancies, especially CRC. One study estimated the risk of CRC to be 15% by age 35 and 68% by age 65.⁹⁶ In another study, GI malignancies (mostly CRC) were diagnosed in 36 (17%) of 218 JPS patients at a mean age of 33 years.⁹⁷ Associated gastric, pancreatic, and duodenal cancers have also been reported. CRCs are thought to arise from malignant transformation of dysplastic

polyps.¹ Adenocarcinomas occur, on average, 15 years after diagnosis of JPS and generally are poorly differentiated or mucinous tumors with a poor prognosis.¹

INVESTIGATIVE STUDIES

Pathologic Findings

The number of polyps seen in JPS patients varies but typically ranges from 50 to 200. The polyps are usually smaller than 1.5 cm but can be as large as 3 cm. Grossly, they appear as red-brown, smooth, pedunculated lesions with lobulated or spherical heads and superficial ulceration; the cut surface demonstrates cystic spaces corresponding to mucus-filled glands. Histologically, polyps are characterized by an inflammatory infiltration of the lamina propria, an attenuated smooth muscle layer, and cystically dilated mucus-filled glands lined by columnar epithelium. Focal epithelial hyperplasia and dysplasia may be present.

Screening and Surveillance

Initial evaluation of the proband and the first-degree relatives, which ideally would be done in the middle to late teenage years, should include colonoscopy, EGD, and a small bowel series. If the

initial evaluation yields negative results, a repeat evaluation should be performed in 3 years, then every 3 years thereafter as long as the results remain negative. If disease is encountered, random biopsies of polyps and intervening mucosa should be performed to detect adenomatous and dysplastic changes. Management depends on the presence of symptoms and on the extent and severity of polyposis. When polyposis is mild, endoscopic management may be feasible. Continued annual surveillance after endoscopic management is required; the surveillance interval may be lengthened to 3 years if subsequent evaluations reveal no disease.^{1,85}

MANAGEMENT

Surgical Therapy

When polyposis is severe or significant symptoms are apparent, prophylactic colectomy with IRA may be considered for suitable surgical candidates. Although rectal polyposis can generally be managed with rigid or flexible proctoscopy, IPAA may be considered if the polyposis is extensive. Continued annual surveillance of the rectal remnant (after IRA) or the ileal pouch (after IPAA) is required initially. Surveillance intervals may be increased to 3 years if subsequent evaluations find no evidence of disease.^{1,85}

15 ADENOCARCINOMA OF THE COLON AND RECTUM

Bruce M. Brenner, MD, FACS, and David M. Ota, MD, FACS

Colorectal cancer (CRC) remains a major public health problem throughout the world. In the United States, CRC is the third most frequently diagnosed cancer in both men and women and the second most common fatal cancer (behind lung cancer).¹ During 2008, there were an estimated 108,000 cases of colon cancer and 41,000 cases of rectal cancer in the United States, resulting in 50,000 total deaths.¹ The cost of treating CRC in the United States is believed to be between 5.5 and 6.5 billion dollars a year.² Worldwide, the risk of death from CRC is highest in developed countries and especially low in Asia and Africa.³

Data from the Surveillance, Epidemiology, and End Results (SEER) program and the National Center for Health Statistics indicate that the overall incidence of and mortality from CRC have been continuously decreasing in the United States since the 1980s among both men and women.⁴ They remain generally higher among men than women. Overall, the incidence of and mortality from CRC are highest among African Americans, somewhat lower among European Americans, and lowest among Asian and Hispanic Americans [see Table 1].⁴ Most CRCs still occur in the distal colon (beyond the splenic flexure), but the incidence of proximal adenocarcinomas relative to that of distal adenocarcinomas has been increasing over the past 30 years [see Figure 1].⁵ The cause of this shift is not known.

Genetics

The development of CRC involves a progression from normal mucosa through adenoma to carcinoma.⁶ A genetic model of colorectal carcinogenesis was first proposed in the early 1990s that describes a sequence of key mutations driving

Figure 1 Shown are the relative frequencies of colorectal cancer for various anatomic subsites of the colon in 1996. For comparative purposes, figures for 1976 are provided in parentheses.

Table 1 Incidence and Mortality of Colorectal Cancer by Race and Sex[†]

Race	Incidence* and APC		Mortality* and APC	
	Male	Female	Male	Female
White	60.6 (−2.2)	44 (−1.8)	22.7 (−2.7)	15.3 (−2.6)
African American	69.4 (−1.0)	52.4 (−1.0)	31.8 (−1.6)	22.4 (−1.9)
Asian/Pacific Islander	45.5 (−2.2)	33.6 (−1.4)	14.4 (−2.1)	10.2 (−2.1)
Hispanic	51.5 (−1.0)	36.2 (−1.2)	16.5 (−2.0)	10.9 (−0.9)

*No./100,000.

APC = annual percentage change.

Figure 2 Diagram illustrates genetic model of colorectal tumorigenesis.⁸

the process of colorectal carcinogenesis [see Figure 2].⁷ This progression was recently reevaluated using large-scale genetic sequencing of multiple lesions from an individual patient.⁸ Using this “comparative lesion sequencing” approach, it is estimated that it takes approximately 17 years for a large adenoma to progress to invasive malignancy but less than 2 additional years to develop the capacity to metastasize.

The process of colorectal carcinogenesis may involve the accumulation of mutations in both tumor suppressor genes and proto-oncogenes, as well as epigenetic phenomena such as DNA hypermethylation or hypomethylation.⁹ The onset of genomic instability increases the mutation rate and accelerates this progression. Inactivation of the adenomatous polyposis coli (*APC*) gene on chromosome 5q is thought to be one of the earliest mutations in sporadic cancers and is seen as a germline mutation in patients with familial polyposis. Mutations in other tumor suppressor genes play an important role in this pathway as well, including mutations in *DCC*, *SMAD2*, and *SMAD4* on chromosome 18q and *p53* on chromosome 17p; these events are thought to occur at a later stage of tumor progression. Mutations in the *K-ras* and *BRAF* oncogenes occur at an intermediate stage. The accumulation of additional mutations (as yet poorly defined) allows metastases to develop.

Microsatellite instability (MSI) is an alternative pathway to genomic instability and subsequent colorectal carcinogenesis. This phenomenon arises from defects in mismatch repair genes, which cause significantly increased mutation rates in comparison with those in normal cells. MSI in hereditary nonpolyposis colorectal cancer (HNPCC) [see Risk Factors, below] is most commonly attributable to germline mutations in the *hMLH1* and *hMSH2* genes.¹⁰ MSI in sporadic CRC is most frequently associated with hypermethylation of the promoter region of the *hMLH1* gene,¹¹ which leads to inactivation of the gene and loss of expression of the hMLH1 protein.

Risk Factors

A number of risk factors for CRC have been described, including a family history of cancer or adenomatous polyps, familial CRC syndromes, inflammatory bowel disease (both ulcerative colitis and Crohn’s disease), and dietary and lifestyle factors.^{12,13} The vast majority of CRCs worldwide are

sporadic—that is, they are not associated with known genetic syndromes. In the United States, no more than 5% of CRCs are associated with known genetic syndromes.

In a meta-analysis of studies addressing CRC risk and family history, the relative risk of CRC in those with an affected first-degree relative was 2.25; this figure rose to 4.25 if more than one relative was involved and to 3.87 if CRC was diagnosed before the age of 45.¹⁴ The National Polyp Study found that the relative risk of CRC was 1.78 in first-degree relatives of patients with adenomatous polyps.¹⁵ In another study, the relative risk of CRC was 1.74 in first-degree relatives of patients with adenomatous polyps and was especially high (4.36) in those diagnosed with polyps at or before the age of 50.¹⁶

The most common of the genetic syndromes known to be associated with CRC is HNPCC, which accounts for the majority of patients with familial CRC. MSI is the characteristic finding of HNPCC, although it is also present in approximately 15% of all sporadic CRCs. HNPCC can be diagnosed clinically on the basis of what are known as the Amsterdam Criteria.¹⁷ Polyposis syndromes (e.g., familial polyposis and juvenile polyposis) account for the remainder of patients with familial CRC syndromes.

As determined by a 2001 meta-analysis, the lifetime risk of CRC for patients with ulcerative colitis is 3.7%, which increases to 5.4% for patients with pancolitis and rises further with greater duration of disease.¹⁸ Despite the common misconception, Crohn’s disease may be associated with a similarly increased risk of CRC.¹⁹

Numerous lifestyle and dietary factors have been put forward as potential causes of increased CRC risk. Lower levels of physical activity and increased body mass are associated with an increased risk of CRC in both men and women.²⁰ The Western-style diet, which is high in calories and fat and low in fiber, is associated with high rates of CRC. There is evidence that increased dietary intake of calcium may confer some protection against the development of CRC and adenomatous polyps. The Calcium Polyp Prevention Study, a large randomized trial done in the United States, reported a small but statistically significant reduction in the incidence of recurrent colorectal adenomas with dietary calcium supplementation.²¹ To date, the evidence from randomized trials has not shown dietary fiber supplementation to have a similar effect. In Japan, where the incidence of CRC has traditionally been

low, CRC has become considerably more common in the past few decades.²² This increased incidence is believed to be the result of post–World War II lifestyle changes (e.g., increased consumption of animal fat and decreased expenditure of energy) that mirror Western habits.

Screening

Early diagnosis of colorectal neoplasms at a presymptomatic stage is important for improving survival. Polypectomy has consistently been shown to decrease the subsequent development of CRC: the National Polyp Study found that the incidence of CRC in patients who underwent colonoscopic polypectomy was as much as 90% less than would otherwise have been expected.²³ Identifying patients with early-stage disease that has not yet metastasized can prevent many CRC-related deaths. Detection of adenomatous polyps prior to the development of invasive cancer has become the focus of screening recommendations. Early detection of and screening for CRC have become important components of routine care and public health programs both in the United States and abroad. The benefits of screening for CRC are especially substantial in patients who are at high risk for CRC (e.g., those with affected first-degree relatives), but even average-risk patients derive significant benefit.

There is no ideal method of screening for CRC that is applicable to all patients. Physical examination is generally not helpful in making the diagnosis; various investigative tests are used instead. In patients at increased or high risk for CRC, colonoscopy is the only recommended screening modality. For average-risk patients, current recommendations divide these tests into those that detect both cancers and premalignant adenomas and those that primarily detect cancer and possibly advanced adenomas.²⁴ Recommended modalities for CRC screening that are also effective in detecting adenomas include colonoscopy, flexible sigmoidoscopy, double-contrast barium enema (DCBE), and virtual colonoscopy (computed tomographic [CT] colonography). Those that are predominantly effective in detecting cancers and some large adenomas include fecal occult blood testing (FOBT) with guaiac-based or immunochemical tests and stool DNA testing.

Only a limited number of randomized trials have evaluated the above screening modalities. Sigmoidoscopy has been shown to decrease both CRC incidence and mortality, but only in case-control studies,²⁵ and colonoscopy detects many CRCs in asymptomatic patients that would not be detected by this procedure.²⁶ FOBT is the sole modality that has consistently been shown to decrease CRC mortality in randomized trials.^{27,28} Few studies directly compare different types of FOBT, but fecal immunochemical tests appear to have a higher sensitivity than guaiac-based tests. The specificity may be slightly lower, however, resulting in more patients requiring follow-up colonoscopy.

Virtual colonoscopy, which uses high-resolution CT scanning to image the colon, has been evaluated in at least two multicenter trials in the United States, with varying results.^{29,30} One of the studies reported a sensitivity and a specificity of 89% and 80%, respectively, for polyps larger than 6 mm and up to 94% and 96%, respectively, for polyps larger than

10 mm.²⁹ The sensitivities were equivalent to those of optical colonoscopy in this group of asymptomatic average-risk patients. The second study, however, found that virtual colonoscopy had a sensitivity of only 39% for lesions larger than 6 mm and 55% for lesions larger than 10 mm.³⁰ Given these divergent findings, it appears that there are issues related to equipment, software, training, and overall sensitivity of the study that remain to be addressed before virtual colonoscopy can be recommended as a routine screening modality. Another consideration is that patients with lesions detected by means of virtual colonoscopy must still undergo optical colonoscopy for treatment or tissue diagnosis.

Fecal DNA assays have been developed to test for mutations in multiple genes known to be involved in colorectal neoplasia and are currently being evaluated in clinical trials.³¹ A study comparing fecal DNA testing with a commercially available multigene panel to guaiac-based testing in asymptomatic patients showed both to have a poor sensitivity in detecting cancers and advanced adenomas detected by screening colonoscopy.³² DNA testing was significantly better, but still only detected 52% of cancers and 18% of advanced adenomas.

Colonoscopy has been consistently shown to be a safe and effective method of CRC screening in asymptomatic, average-risk patients. CT colonography has replaced barium enema as the radiologic screening test of choice but has not been clearly demonstrated to be equivalent to colonoscopy. FOBT and DNA testing are less sensitive and specific than colonoscopy in addition to being relatively ineffective in detecting premalignant polyps. These other modalities may be useful in patients who are unable or unwilling to comply with endoscopic screening.

Many groups have advocated CRC screening, and published guidelines are available from several organizations, including a collaborative guideline published by the American Cancer Society, the US Preventive Services Task Force, and the American College of Radiology.³³ Others include the American College of Gastroenterology³⁴ and the National Comprehensive Cancer Network (NCCN).³⁵ All of these guidelines recommend that screening begin at age 50 for average-risk patients with colonoscopy at 10-year intervals. The recommended screening options in patients unwilling or unable to undergo colonoscopy are fairly consistent among the various organizations and include (1) FOBT yearly, (2) flexible sigmoidoscopy every 5 years, (3) yearly FOBT and flexible sigmoidoscopy every 5 years, (4) DCBE every 5 years, and (5) CT colonography every 5 years. In high-risk patients (e.g., those with a family history of CRC), screening may begin at an earlier age—generally at age 40 or 10 years younger than the age of the affected first-degree relative and with shorter, 5-year intervals. There are also specific intensive screening and follow-up regimens for patients with known or suspected familial cancer syndromes.

Clinical Evaluation

As a consequence of the use of screening modalities, patients with CRC are often asymptomatic at diagnosis. Some CRC patients present with occult gastrointestinal bleeding and anemia. Many patients do not exhibit symptoms

until relatively late in the course of the disease. The duration of symptoms, however, is not necessarily associated with the stage of the tumor.³⁶

The most common symptoms of CRC are bleeding per rectum, abdominal or back pain, and changes in bowel habits or stool caliber. Other symptoms are fatigue, anorexia, weight loss, nausea, and vomiting. Some patients present with acute bowel obstruction or perforation.

Staging and Prognosis

Accurate staging of CRC is extremely important for determining patient prognosis and assessing the need for adjuvant therapy. Traditionally, staging of CRC has been based on modifications of the Dukes classification, which was initially developed as a prognostic tool for rectal cancer in the 1930s.³⁷ Since this classification was first implemented, it has undergone multiple modifications, of which the most widely used is the modified Astler-Collier system, initially introduced in the 1950s.³⁸ Currently, the TNM classification, developed by the American Joint Committee on Cancer (AJCC) and the International Union against Cancer (UICC), is the preferred staging system [see Table 2 and Table 3].³⁹ This system takes into account the depth of penetration into the bowel wall (T) [see Figure 3], the presence and number of involved mesenteric nodes (N), and the presence of distant metastases (M).

CLINICAL STAGING

Clinical staging is based on the history and the physical examination, endoscopic findings, and biopsy results. If colonoscopy cannot be completed, an air-contrast barium enema study should be performed to evaluate the remainder of the colon. Additional staging information may be obtained by means of imaging studies (e.g., roentgenography, CT, magnetic resonance imaging [MRI], and positron emission tomography [PET]). A chest x-ray is routinely obtained to rule out metastases and prepare for operation.

There is some debate regarding the utility of preoperative CT scans in the management of primary colon cancer. The rationale for obtaining these scans includes evaluation of potential metastatic disease and assessment of the local extent of disease. In a 2002 study of preoperative CT in patients

Table 2 American Joint Committee on Cancer TNM Clinical Classification of Colorectal Cancer

Primary tumor (T)	
T0	No evidence of primary tumor
Tis	Carcinoma in situ, intraepithelial or invasion of lamina propria
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through muscularis propria
T4	Tumor invades other organs or perforates visceral peritoneum
Regional lymph nodes (N)	
N0	No regional lymph node metastases
N1	Metastases in 1 to 3 regional lymph nodes
N2	Metastases in 4 or more regional lymph nodes
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

Table 3 American Joint Committee on Cancer Staging of Colorectal Cancer³⁹

Stage	T	N	M
0	Tis	N0	M0
I	T1, T2	N0	M0
IIA	T3	N0	M0
IIB	T4	N0	M0
IIIA	T1, T2	N1	M0
IIIB	T3, T4	N1	M0
IIIC	Any T	N2	M0
IV	Any T	Any N	M1

with intraperitoneal colon cancer, however, the results of the imaging changed management in only 19% of patients, and CT had a sensitivity of only 78% for all metastatic disease.⁴⁰ Nonetheless, many surgeons routinely perform staging CT in

Figure 3 Classification of colorectal cancer takes into account the depth of tumor penetration and involvement of lymph nodes.

patients with primary colon cancer. PET is a sensitive study, but its routine use for staging primary CRC is not generally recommended. PET may be considered for high-risk patients in whom the detection of metastases would change initial management.⁴¹

In cases of rectal cancer, locoregional staging may significantly affect therapeutic decision making. Such staging includes determination of the depth of invasion of the rectal wall and the degree of regional node involvement. Modalities commonly used include CT, MRI, and endoscopic ultrasonography (EUS). In a 2004 meta-analysis that examined the relative utility of each of these studies in rectal cancer staging, EUS proved to be the most accurate technique for evaluating muscularis propria involvement and perirectal tissue invasion.⁴² The various techniques were equally accurate in assessing lymph node involvement, with none of them being highly sensitive.

PATHOLOGIC STAGING

Definitive pathologic staging is carried out after surgical exploration and examination of the resected specimen. The final stage of the cancer is then determined on the basis of the TNM system [see Table 2 and Table 3]. Survival is correlated with the stage of the tumor [see Figure 4 and Figure 5]. In the current (sixth) edition of the AJCC staging system, stage II is subdivided into stages IIA and IIB, and stage III is subdivided into stages IIIA, IIIB, and IIIC on the basis of both the extent of wall penetration and the number of nodes involved.³⁹ These changes were implemented as a result of studies demonstrating differences in survival among these subgroups [see Figure 6].⁴³

Numerous other criteria have been evaluated as additional prognostic factors in CRC. The degree of lymphatic invasion and the extent of vascular invasion are important adjuncts to the TNM staging system and are incorporated in the current schema.³⁹ Certain histologic types, including signet-ring and mucinous carcinomas, are associated with poor outcomes. The preoperative serum carcinoembryonic antigen

Figure 4 Shown are 5-year survival rates for cases of colon cancer diagnosed in 1,735 US hospitals in 1995 and 1996.

Figure 5 Shown are 5-year survival rates for cases of rectal cancer diagnosed in 1,683 US hospitals in 1995 and 1996.

Figure 6 Shown are 5-year survival rates for cases of stage III colon cancer diagnosed between 1987 and 1993, stratified according to stage III subgroups established by the 6th edition of the AJCC Staging Manual.³⁹

(CEA) level may be an independent prognostic factor that is predictive of resectability and the presence of distant metastases.⁴⁴

MOLECULAR MARKERS

Various molecular markers have been investigated with respect to prognosis and response to therapy in CRC patients. Unfortunately, there are conflicting data on the prognostic impact and clinical utility of most of these markers. As noted [see Risk Factors, above], MSI is seen in as many as 15% of patients with sporadic CRC. Patients with MSI typically have proximal, poorly differentiated tumors with mucinous or signet-ring components, but they usually exhibit improved overall survival.⁴⁵ These patients may be less sensitive to 5-fluorouracil (5-FU)-based chemotherapy.⁴⁶

The long arm of chromosome 18 (18q) harbors at least three candidate tumor suppressor genes, including *DCC*, *SMAD2*, and *SMAD4*. Deletions of chromosome 18q in CRC patients are associated with decreased survival. One study found that patients with stage II cancers and 18q allelic loss had a prognosis similar to that of patients with stage III disease.⁴⁷ In addition, *p53* mutations and overexpression are associated with poor outcomes in CRC.⁴⁸ Thymidylate synthase is an enzyme active in DNA synthesis that is targeted by 5-FU and similar chemotherapeutic agents. Overexpression of this enzyme is associated with a poor prognosis but also with improved sensitivity to 5-FU-based chemotherapy.⁴⁹

All of these molecular alterations, as well as others (e.g., *K-ras* mutations and 5q deletions), are commonly observed in CRC patients, but further study is required to establish their real prognostic significance.

Management of Colon Cancer

SURGICAL THERAPY

Surgery with curative intent remains the mainstay of therapy for colon cancer [see Figure 7]. Complete R0 resection (leaving no gross or microscopic disease) with wide margins along the bowel wall, coupled with regional lymphadenectomy, is the standard of care. The major arterial vessels supplying the segment of the colon containing the tumor should be excised at their origins. A minimum margin of 5 cm of normal bowel on each side of the tumor is considered adequate.

Extent of Resection

The standard extent of resection for various colon cancers has been defined. For tumors of the cecum and the ascending colon, a right hemicolectomy that includes the right branch of the middle colic artery at its origin should be performed. For tumors of the hepatic flexure, an extended right colectomy that includes the entire middle colic artery is indicated. For tumors of the transverse colon, an extended right or left colectomy or a transverse colectomy may be performed. For tumors of the splenic flexure region, a left hemicolectomy is performed, and for sigmoid tumors, a sigmoid colectomy is performed.

In patients who have small or flat tumors or who are undergoing resection after a polypectomy, intraoperative identification of the tumor may be difficult. This is especially true with laparoscopic procedures, in which the bowel often cannot be palpated. If the lesion is in the cecum, the ileocecal valve and the appendiceal orifice are visualized endoscopically, and localization of the tumor is simple. If the lesion is at another location, endoscopic measurements of the distance from the anus or estimates of the location of the tumor may be inaccurate. Endoscopic tattooing, a process in which an agent is injected into the bowel wall submucosally at or near the site of the lesion, has been employed to facilitate intraoperative identification of the tumor site. India ink is the agent most commonly used for this purpose and generally yields excellent results.⁵⁰ As an alternative, many institutions use a commercially available sterile suspension of carbon particles, which is also very safe and effective.⁵¹ Intraoperative endoscopy is another option for locating these lesions.

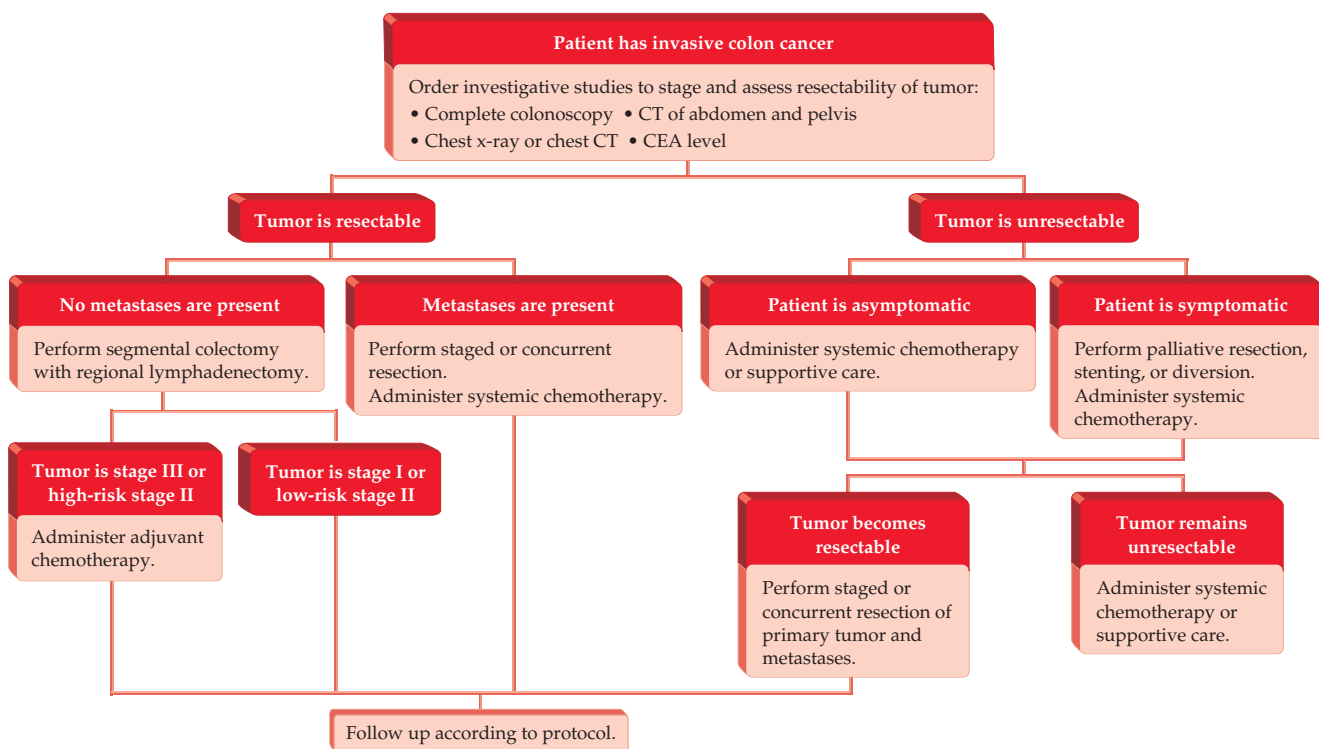

Figure 7 Algorithm outlines treatment of colon cancer. CEA = carcinoembryonic antigen; CT = computed tomography.

Surgical Staging

The selection of patients for adjuvant therapy relies heavily on accurate staging. A significant percentage of patients with early-stage node-negative disease present with recurrences or metastases; such a presentation implies that the patients had occult metastatic disease at the time of operation. Surgical resection of CRC should include division of the appropriate mesenteric vessels at their origins, along with resection of the regional nodes. Optimal staging of CRC patients, especially with regard to nodal status, remains controversial. One area of debate is the number of nodes that must be examined to confirm node negativity. This number depends both on the surgeon's technique (i.e., how many nodes were resected) and on the pathologist's efforts to harvest nodes from the specimen. Most groups recommend analysis of at least 12 nodes to confirm node negativity.⁵²

Because of the importance of nodal status, ultrastaging of harvested nodes with techniques such as serial sectioning, immunohistochemistry (IHC), and reverse transcriptase polymerase chain reaction (RT-PCR) has been proposed as a means of detecting micrometastases. All of these techniques may result in upstaging of patients who are node negative on standard pathologic analysis, which involves only bivalving the nodes and examining a limited number of sections. The prognostic impact of micrometastases that are detected only by IHC or RT-PCR and are not verified by hematoxylin-eosin staining remains unclear. It is impractical to perform these assays on all nodes harvested; accordingly, the use of lymphatic mapping to identify sentinel lymph nodes (SLNs) has been proposed as a means of selecting a small number of nodes for further analysis.

SLN biopsy in the setting of CRC remains investigational. Lymphatic mapping may be done with either in vivo or ex vivo injection of tracer dye. The dye rapidly diffuses through the lymphatic vessels, and SLNs can be identified and marked in the mesocolon within minutes. This procedure has been shown to be feasible in a number of studies⁵³; however, its sensitivity and false negative rates have been variable. In a 2004 multicenter trial, SLN biopsy with serial sectioning had a false negative rate of 54% in patients with node-positive colon cancer.⁵⁴ In a large single-institution trial, both SLNs and non-SLNs were studied with serial sectioning and IHC in patients who were node negative on routine pathologic analysis⁵⁵; 19.5% of patients were upstaged by the combination of serial sectioning and IHC of SLNs. These results imply that the main role of this technique may be in upstaging patients who are node negative on routine pathologic analysis. Further study is required before the use of SLN techniques in the context of CRC becomes standard clinical practice.

Occult metastatic disease may also be present in the peritoneal cavity or systemically in the blood or bone marrow at the time of operation. The presence of tumor cells in the peritoneum may be detected by performing cytologic analysis of washings done at the time of operation. In one study, disseminated tumor cells were identified in peritoneal washings or blood in 25% of patients, and their presence was found to be an independent prognostic factor for survival.⁵⁶ In another study, patients with positive peritoneal washings had significantly higher rates of local recurrence and peritoneal carcinomatosis but manifested no differences in survival.⁵⁷ Again,

further study is required before these assays can be routinely used for staging CRC.

Laparoscopic versus Open Colectomy

At present, open colectomy remains the most widely used treatment of resectable colon cancer. Initially, there were concerns about port-site recurrences,⁵⁸ but current data suggest that these concerns are unfounded.⁵⁹ With respect to comparative cost, data from a subset of patients in the European Colon cancer Laparoscopic or Open Resection (COLOR) trial demonstrated that although the total cost to society from laparoscopic colectomy is similar to that from open colectomy, the costs to the health care system are significantly higher with the former.⁶⁰ The Clinical Outcomes of Surgical Therapy (COST) study group, a large, randomized, multicenter trial conducted in the United States, found that laparoscopic-assisted colectomy conferred only minimal (although statistically significant) short-term quality-of-life benefits when compared with open colectomy.^{61,62} Cancer-specific outcomes (e.g., recurrence rates, wound recurrences, and overall survival rates) were similar at 3 years with the two approaches, leading to the conclusion that laparoscopic colectomy is an acceptable alternative to open colectomy.⁶² This finding was confirmed at 7 years of median follow-up with no difference demonstrated in disease-free or overall survival.⁶³ The COLOR trial could not rule out a small difference in disease-free survival at 3 years in favor of open colectomy, but the authors concluded that this is "clinically acceptable."⁶⁴ The CLASSIC trial from the United Kingdom showed equivalent disease-free and overall survival at 3 years of follow-up.⁶⁵ Based on these and other studies, laparoscopic colectomy has become accepted as equivalent to open colectomy for the treatment of colon cancer.

Special Situations

Obstructing and perforated cancers Obstructing and perforated colon cancers are associated with a poor prognosis and with increased surgical morbidity (as a consequence of the need for emergency surgery). Perforation can occur either via direct erosion of the tumor through the wall of the colon or secondary to obstruction with resultant bowel distention proximal to the tumor. Patients with perforated colon cancer are managed with emergency laparotomy, washout, and resection of the primary lesion to prevent further soilage. A diverting stoma is usually indicated, with either a Hartmann pouch or a mucous fistula constructed distally. Select patients may be managed by means of primary anastomosis, with or without a proximal diverting colostomy or ileostomy.

Obstructing right-side cancers (up to the splenic flexure) can usually be treated with resection and primary anastomosis. The traditional emergency treatment of obstructing left-side colon cancers is a diverting colostomy, with or without resection of the lesion. In many such cases, the stoma is never taken down. Some surgeons advocate emergency treatment of these lesions with total abdominal colectomy and ileorectal anastomosis as a means of improving outcomes.⁶⁶ Another treatment option is primary resection and anastomosis, with or without on-table intestinal lavage. Yet another option for managing obstructing left-side colon and rectal cancers is the use of colorectal stents with the aim of avoiding emergency

surgery. Stents can serve as a bridge to definitive resection by decompressing the colon and thereby allowing subsequent bowel preparation. In patients with advanced disease, stents may also be employed for palliation as an alternative to surgical resection or a diverting stoma.

Synchronous primary colorectal cancers The incidence of synchronous CRCs is reported to range from 3 to 5%^{67,68} but may be as high as 11%.⁶⁹ Stage for stage, there appear to be no differences in survival between synchronous cancers and single primary cancers.^{70,71} Synchronous adenomatous polyps are present in as many as 35% of patients undergoing surgical treatment of CRC.^{68,71} In one study, the presence of synchronous lesions made the surgical procedure more extensive than was initially planned for resection of the primary tumor in 11% of patients.⁶⁸

Most synchronous polyps are identified on preoperative colonoscopy, and the colon can often be cleared of these lesions before operation. Management of adenomas not amenable to endoscopic resection and management of synchronous cancers are more challenging. Each primary cancer must be managed surgically according to sound oncologic principles. One option is to perform multiple segmental resections with multiple anastomoses. Another is to perform an extended resection that encompasses all of the lesions or even total abdominal colectomy if needed. The presence of a rectal cancer and a second synchronous lesion makes surgical treatment even more challenging, especially if sphincter preservation and a low rectal or coloanal anastomosis are contemplated.

ADJUVANT THERAPY

Significant progress in systemic adjuvant therapy for patients undergoing resection of a colorectal adenocarcinoma has been made in the past 20 to 30 years, primarily through a series of phase III randomized trials and the development of new drugs. The evolution of adjuvant therapies is likely to continue for the foreseeable future, and surgeons will play a pivotal role as the primary entrance point for standard adjuvant therapy and new phase III randomized trials. Surgeons' awareness of past accomplishments, current study findings, and future phase III trials is crucial for improving the survival of potentially cured patients.

The 5-year survival rate after resection of colon cancer is inversely correlated with the pathologic stage [see *Figure 4*]. The diminishing 5-year survival rates for stage II and III colon cancer became the basis of several phase III randomized trials designed to test the hypothesis that postoperative systemic adjuvant chemotherapy would significantly improve survival in patients with resected but high-risk cancers. Multi-institutional, cooperative cancer group trials were necessary to obtain populations large enough to test this hypothesis. The North Central Cancer Treatment Group (NCCTG) initiated a randomized trial of postoperative systemic adjuvant 5-FU plus levamisole for Dukes stage B and C (AJCC stage II and III) colon carcinomas.⁷² Patients were randomly assigned to receive either levamisole alone or 5-FU plus levamisole. Overall survival was significantly improved in stage C patients treated with 5-FU plus levamisole. This was

the first randomized trial to demonstrate the efficacy of systemic adjuvant therapy.

The NCCTG trial led to second-generation trials of adjuvant therapy for patients with resected colon cancers. In one such study, patients with high-risk stage II or stage III colon cancer were randomly assigned to receive either 5-FU plus leucovorin and levamisole or 5-FU plus levamisole.⁷³ Survival rates after 12 months of adjuvant chemotherapy were no better than those after 6 months of chemotherapy; however, 5-FU plus levamisole proved to be inferior to 5-FU plus leucovorin and levamisole with respect to survival.

National Surgical Adjuvant Breast and Bowel Project (NSABP) protocol C-04 randomly assigned Dukes stage B and C colon cancer patients to receive (1) postoperative 5-FU plus leucovorin, (2) 5-FU plus levamisole, or (3) 5-FU plus leucovorin and levamisole.⁷⁴ A slight improvement in 5-year disease-free survival was noted with 5-FU plus leucovorin, but overall 5-year survival did not differ significantly among the three treatment arms. Accordingly, 5-FU plus leucovorin became the standard adjuvant regimen.

Intergroup Trial 0089 randomly assigned patients with high-risk stage II and III disease to receive either 5-FU plus high-dose leucovorin or 5-FU plus low-dose leucovorin. The investigators concluded that (1) the high-dose and low-dose regimens were equivalent, (2) a regimen consisting of four cycles of 5-FU with high-dose weekly leucovorin was equivalent to the low-dose leucovorin Mayo Clinic regimen, and (3) the addition of levamisole to the 5-FU plus leucovorin regimen did not improve survival.

These clinical trials established 5-FU plus leucovorin as standard therapy for patients with high-risk stage II and stage III colon cancer. A new series of studies has now provided data regarding newer agents such as oxaliplatin, irinotecan, bevacizumab, and cetuximab. The MOSAIC trial, a large multinational trial,⁷⁵ and the NSABP C-07 trial⁷⁶ both demonstrated improved outcomes with the addition of oxaliplatin to 5-FU-based regimens. In the MOSAIC trial, the addition of oxaliplatin resulted in a 5.9% increase in disease-free survival at 5 years.⁷⁷ There was also a statistically significant 4.6% improvement in overall survival seen in stage III patients with a 6-year median follow-up. Oxaliplatin is now considered a standard component of adjuvant therapy protocols for CRC. Irinotecan has not been shown to improve survival in the adjuvant setting and is associated with increased toxicity⁷⁸ and is therefore not generally used. Addition of targeted agents such as bevacizumab, which is a vascular endothelial growth factor antibody, and cetuximab, which is an epidermal growth factor receptor antibody, is currently being studied in trials.

Routine use of systemic adjuvant therapy for stage II colon cancer remains controversial. Patients with stage II colon cancers, including those at high risk (e.g., those who present with large bowel obstruction or perforation), are typically included in adjuvant chemotherapy trials. A meta-analysis of stage II patients included in NSABP colon cancer trials demonstrated that adjuvant chemotherapy did confer a survival benefit at this disease stage.⁷⁹ This study was criticized, however, for having included patients from trials that lacked a surgery-only arm, as well as from trials that employed outmoded chemotherapeutic regimens.⁸⁰ Another meta-analysis, which included only trials that compared 5-FU plus leucovorin with observation after

curative resection in stage II patients, found no statistically significant survival benefit with chemotherapy.⁸¹ A 2004 meta-analysis formulated recommendations on this controversial topic and provided a Web-based tool for calculating risk.⁸² This report included data from seven randomized trials that compared surgery alone with surgery plus chemotherapy. Patients with node-negative disease derived a much lower reduction in risk and no statistically significant improvement in overall survival. The authors concluded that the use of postoperative adjuvant chemotherapy for stage II colon cancer patients should be individualized on the basis of the estimated prognosis and the potential treatment benefit. In the MOSAIC trial, there was no long-term overall survival benefit in stage II patients receiving oxaliplatin compared to 5-FU and leucovorin alone.⁷⁷

In summary, postoperative systemic adjuvant therapy is the standard of care in patients with stage III disease. In stage II colon cancer patients who have undergone complete surgical resection, the relative risk of recurrence is small enough that adjuvant chemotherapy yields relatively little benefit in terms of survival. There is, however, a subgroup of patients who have recognized prognostic factors that significantly reduce survival and in whom adjuvant therapy is therefore more likely to be beneficial. These risk factors include (1) bowel obstruction, (2) colonic perforation, (3) high-grade or lymphovascular invasion, and (4) the presence of fewer than 12 lymph nodes in the resected specimen. Additional risk factors such as chromosome 18 deletions and MSI continue to be evaluated.

Management of Rectal Cancer

Rectal cancer presents special management issues with respect to local recurrence after surgical resection. With cancer of the intraperitoneal colon, local recurrence is rare. With rectal cancer, however, surgical treatment alone results in recurrence rates of 16.2% after low anterior resection (LAR) and 19.3% after abdominoperineal resection (APR).⁸³ Higher stages are associated with higher recurrence rates: 8.5% for Dukes stage A, 16.3% for stage B, and 26% for stage C.⁸³ Multimodality management, including adjuvant radiation therapy or chemotherapy (or both) in combination with appropriate operative therapy, can reduce local recurrence rates significantly.

SURGICAL THERAPY

Extent of Resection

Sphincter preservation has become a major goal in the multimodality treatment of rectal cancer. Surgical procedures are chosen and performed with this goal firmly in mind.

Radical resection Traditionally, tumors of the rectum have been treated with either LAR or APR [see Figure 8]; in numerous series, APR rates of 60% or higher have been reported. Surgical techniques such as stapled or handsewn coloanal anastomoses, when combined with total mesorectal excision (TME), have led to excellent cancer-related outcomes without the need for permanent colostomy. The use of preoperative chemoradiation therapy for tumor downstaging may also reduce the need for APR.⁸⁴

The morbidity associated with radical rectal resection can be substantial. Anastomotic leakage rates vary widely, ranging from less than 10% to more than 30% after resection with anastomosis. Leaks can lead to substantial morbidity and mortality and can necessitate reoperation. Such concerns have prompted the use of temporary diverting ileostomies or colostomies in patients with low rectal anastomoses. Defunctioning stomas may be overused, however, thereby increasing the cost of care in low-risk patients.⁸⁵ Preoperative chemoradiation therapy has not been shown to increase anastomotic leakage rates. Urinary and sexual dysfunction are also fairly common after radical resection of rectal cancer. Autonomic nerve preservation in conjunction with TME may improve the functional results of these procedures.⁸⁶ The use of local resection techniques (see below) is another means of reducing surgical morbidity and mortality in rectal cancer patients.

Local excision Local excision—including transanal, transsphincteric, and transcoccygeal techniques, as well as transanal endoscopic microsurgery (TEM)—is another option for curative resection of low rectal cancers with preservation of sphincter function. These procedures were initially implemented for local control in patients who were medically unfit for or unwilling to undergo major resections. Transsphincteric and transcoccygeal resections have been associated with an increased incidence of complications, including fecal fistulas and incontinence, and have largely been abandoned now that other, better techniques are available.

Local excision with curative intent is generally reserved for the treatment of early-stage (T1-2N0) lesions and remains controversial even in these patients. Selection of patients for these procedures is critical and is based on preoperative staging and on the probability of harboring nodal metastases, which increases with the T stage. EUS and endorectal coil MRI have become an important staging procedure in these patients, both for assessing the depth of tissue invasion and for detecting the presence of nodal disease. CT is generally performed to rule out distant metastases. Palliative procedures (e.g., fulguration and endocavitary irradiation) may also be considered in patients who are unfit for major surgery.

Several criteria have been established to identify patients who may be candidates for transanal excision (TAE) (NCCN guidelines).⁸⁷ According to guidelines published by the NCCN, the lesion must be no more than 3 cm in diameter, must encompass no more than 30% of the circumference of the rectum, and must be less than 8 cm from the anal verge. With the advent of TEM, these criteria have been expanded to include patients with higher lesions. Poorly differentiated tumors and the presence of lymphovascular invasion may also be associated with increased nodal involvement and higher recurrence rates. At least two prospective trials have reported their results with TAE.^{88,89} Local recurrence rates ranged from 5 to 7% for T1 lesions treated with surgery alone. The results were not as promising for T2 lesions: local recurrence rates ranged from 14 to 16%, even when adjuvant radiation or chemoradiation therapy was provided. Long-term follow-up data were recently published for one of these studies, showing local recurrence rates of 8 and 18% for T1 and T2 lesions, respectively, with a median follow-up of 7 years.⁹⁰ In a recent nationwide cohort study using National Cancer Data Base

Figure 8 Algorithm outlines treatment of rectal cancer. APR = abdominoperineal resection; CEA = carcinoembryonic antigen; CT = computed tomography; LAR = low anterior resection; MRI = magnetic resonance imaging; TAE = transanal excision; TEM = transanal endoscopic microsurgery. *High-risk features include a positive margin, lymphovascular invasion, and poorly differentiated or mucinous histopathology.

data, local excision resulted in significantly higher local recurrence rates than radical surgery for both T1 (12.5 versus 6.9%) and T2 (22.1 versus 15.1%) tumors.⁹¹ Five-year overall survival rates were not significantly different, however.

The use of local excision in patients with more locally advanced disease is even more controversial. Such patients

are at considerably greater risk for nodal metastases and thus for local recurrence even after adequate resection of the primary lesion. Traditionally, local excision in patients with locally advanced disease has been associated with unacceptably high recurrence rates. Some authors advocate combining chemoradiation therapy with local excision to manage these

patients. In a 2004 retrospective series, the results of local excision were comparable to those of radical resection in T3 patients who had a good response to preoperative chemoradiation therapy and who refused or were medically unfit for major surgery.⁹² The role of local excision in these patients remains poorly defined.

Patients undergoing local resection must receive careful follow-up, including digital examination, measurement of CEA levels, proctoscopy, and, possibly, transanal ultrasonography. A subset of these patients with local-only recurrences who are medically fit for surgery may be candidates for resection. At present, few good data are available on the results of salvage surgery for local recurrence after local excision of rectal cancer, but it is unlikely that outcomes are equivalent to those of initial radical resection.⁹³

Importance of Radial and Distal Resection Margins

There has been a great deal of debate about what constitutes an adequate margin of resection in surgical treatment of rectal cancer. With respect to distal margins, 2 to 5 cm has traditionally been considered to be the minimum necessary for curative resection. Growing interest in sphincter preservation has led investigators to consider smaller distal margins (i.e., < 2 cm). Studies have shown that clear margins smaller than 2 cm are not associated with higher local recurrence rates or reduced survival.⁹⁴ Subsequent reports have suggested that even smaller histologically negative margins (i.e., < 1 cm) may be adequate in patients receiving adjuvant chemoradiation therapy.^{95,96}

The importance of radial margin involvement after rectal cancer resection was not recognized until comparatively recently.⁹⁷ Radial margins are assessed by means of serial slicing and evaluation of multiple coronal sections of the tumor and the mesorectum.⁹⁷ Involvement of radial margins is a predictor of both local recurrence and survival after potentially curative rectal cancer surgery⁹⁸ and may be associated with an increased risk of distant metastases.⁹⁹ Radial margins smaller than 2 mm are associated with increased local recurrence rates.⁹⁹ Adjuvant radiation therapy does not compensate for the adverse impact of positive margins on local recurrence rates.¹⁰⁰

ADJUVANT AND NEOADJUVANT THERAPY

Adjuvant therapy for rectal cancer has focused on both locoregional control of disease and treatment of systemic disease. Several large studies have evaluated local recurrence of disease after surgical resection alone. Local failure rates of 30 to 40% for T2N0 disease and 50 to 70% for node-positive disease strongly suggested that postoperative adjuvant therapy was needed.^{101–103} In distinct contrast to these data, however, other series in which TME was performed reported extremely low local recurrence rates with surgery alone.^{104,105}

A series of randomized trials were conducted to assess adjuvant therapy for rectal cancer. Initial studies reported a decrease in local recurrence rates with postoperative radiation therapy.^{106,107} In a multi-institutional trial conducted by the NCCTG, the combination of 5-FU with radiation therapy led to improvements in local control rates and in survival.¹⁰⁸ These results were confirmed in large intergroup trials, the results of which indicated that continuous infusion of 5-FU during radiation therapy resulted in significantly better disease-free survival and overall survival than bolus infusion of 5-FU.

Simultaneously with the ongoing development of postoperative locoregional adjuvant therapy for rectal cancer, interest in preoperative (neoadjuvant) therapy has been growing. Preoperative radiation therapy has been associated with excellent local control of disease, sphincter preservation, and acceptable postoperative recovery. There is evidence that rectal adenocarcinoma is sensitive to preoperative radiation therapy, with or without 5-FU. Pathologic complete response rates of 10 to 20% have been noted in resected rectal specimens¹⁰⁹; pathologic complete response is associated with improved outcomes.¹¹⁰

Perhaps the strongest reason to consider preoperative therapy for rectal cancer is its potential for inducing significant tumor regression before surgical resection. Such regression makes clear radial and distal margins easier to obtain. Moreover, tumor regression with preoperative therapy may result in higher sphincter preservation rates. In many published series, the APR rate in rectal cancer patients is between 40 and 60%; more aggressive preoperative efforts to induce regression may give surgeons a better chance to achieve sphincter preservation without compromising local control of disease.¹⁰⁹ One advantage of the postoperative approach is that the disease is more accurately staged before adjuvant therapy begins; thus, patients with early-stage disease are less likely to be overtreated. Data continue to accumulate on the relative merits of preoperative versus postoperative adjuvant treatment of rectal cancer.

Two Swedish studies considered the role of preoperative radiation therapy in treating rectal cancer. The first demonstrated that a short course of preoperative radiation therapy (2.5 Gy in five fractions) was comparable to high-dose postoperative radiation therapy (60 Gy over a period of 8 weeks). The local recurrence rate was significantly lower with the short-course preoperative regimen (12% versus 21%), and there was no overall survival difference between the two regimens.¹¹¹ In the second trial, patients received either a short course of preoperative radiation therapy or surgery alone.¹¹² The local recurrence rate at a median follow-up of 13 years was 9% for preoperative therapy plus surgery compared with 26% for surgery alone. The combined regimen also resulted in significantly better overall survival (38% versus 30%).

The relative benefits of preoperative versus postoperative radiation therapy have been elucidated by the findings from more recent trials. A 2004 German trial randomly assigned patients to receive either preoperative or postoperative 5-FU plus radiation followed by systemic 5-FU therapy.⁸⁴ This study was limited to patients with locally advanced disease, including those who had T3 or T4 disease or were node positive on ultrasonography. TME was performed in all patients and was done 6 weeks after treatment in patients receiving preoperative chemoradiation therapy. The primary end point of this study was overall survival; secondary end points included disease-free survival, local and distant control of disease, sphincter preservation, toxicity of adjuvant therapy, surgical complications, and quality of life. There was no difference between the preoperative group and the postoperative group with respect to 5-year survival, but the local recurrence rate was significantly lower with the former (6% versus 13%), as were both the short-term and the long-term toxicity of adjuvant therapy.

Although, overall, the rates of complete (R0) resection and sphincter preservation were similar in the two groups, the APR rate was significantly lower in patients determined by the surgeon to require APR before randomization.

A large multinational trial of preoperative radiation versus selective postoperative chemoradiation demonstrated a significantly decreased local recurrence rate and improved disease-free survival in the preoperative radiation group.¹¹³ Overall survival was not significantly different. A French trial studied the benefits of adding chemotherapy to preoperative radiation.¹¹⁴ The addition of 5-FU-based chemotherapy at any point in the patients' treatment resulted in a significant improvement in local recurrence but no difference in survival.

The use of adjuvant 5-FU-based chemotherapy and radiation, particularly in the preoperative setting, in the treatment of rectal cancer has demonstrated clear benefit in multiple trials. Studies are currently in progress, including the NSABP R-04, to evaluate the benefits of additional chemotherapeutic agents in combination with preoperative radiation.

Special Considerations

SYNCHRONOUS METASTATIC (STAGE IV) DISEASE

As many as 20% of CRC patients have metastatic disease at the time of initial presentation. The need for surgical intervention in this group of patients is not well defined. Clearly, surgical resection or diversion is indicated in patients who present with significant bleeding, perforation, or obstruction. In asymptomatic patients with unresectable metastatic disease, the role of surgical resection of the primary lesion remains controversial. In patients with resectable metastatic disease (e.g., isolated liver or lung metastases), curative resection may be undertaken.

In a retrospective review of patients presenting with unresectable stage IV CRC, there was no difference in survival between those who were initially managed surgically and those who were initially managed nonoperatively.¹¹⁵ In the surgical group, the morbidity was 30% and the mortality was 5%. Only 9% of the nonoperative patients subsequently required surgical intervention for bowel obstruction. In another retrospective series, patients managed surgically had significantly better overall survival than those managed nonoperatively but had a lesser tumor burden¹¹⁶; 29% of the nonoperative patients eventually required surgery for bowel obstruction. When prognostic factors were evaluated in the surgical arm of this series, the only factor associated with improved outcomes was a less than 25% extent of liver involvement. On the basis of these and other studies, asymptomatic patients with unresectable metastatic CRC should be managed selectively: those with limited tumor burdens may benefit from surgical treatment, whereas those with more extensive disease (especially extensive liver involvement) may initially be managed nonoperatively.

Management of patients with synchronous resectable isolated liver metastases continues to evolve. Many studies have documented improved survival after liver resection in patients with metastatic disease that is confined to the liver. Patients presenting with synchronous lesions have a worse prognosis than those presenting with metachronous lesions.¹¹⁷ Many of these patients have been managed with staged resections of the

primary cancers and the liver metastases. Several groups have reported that such combined procedures do not substantially increase surgical morbidity and mortality or compromise cancer survival.^{118,119} These combined procedures should be done only in carefully selected patients at specialized centers with significant experience in resection of both CRC and liver tumors.

PERITONEAL CARCINOMATOSIS

Peritoneal carcinomatosis develops in approximately 13% of all CRC patients.¹²⁰ The survival rate of patients who present with peritoneal carcinomatosis from CRC is dismal. In patients with stage IV CRC, the presence of carcinomatosis is associated with a significant reduction in survival (from 18.1 months to 6.7 months).¹²¹ Treatment has traditionally included systemic chemotherapy, with surgery reserved for palliation of symptoms such as bowel obstruction. Newer chemotherapy regimens that include agents such as oxaliplatin may improve survival, but they certainly are not curative.

Peritoneal carcinomatosis is often associated with hematogenous metastases, but in some 25% of patients, the peritoneal cavity is the only site of disease. Several groups have advocated the use of cytoreductive surgery and hyperthermic intraperitoneal chemotherapy (HIPEC) as a means of improving survival in these patients.¹²² This treatment, however, is associated with significant morbidity and mortality.¹²³ A randomized trial from the Netherlands that compared cytoreduction surgery plus HIPEC with systemic chemotherapy plus palliative surgery found that patients in the former group exhibited a statistically significant improvement in median survival (22.3 months versus 12.6 months).¹²⁴ At 8 years of follow-up, a significant improvement in median disease-specific survival was maintained.¹²⁵ Cytoreductive surgery plus HIPEC seems to be a viable option for the treatment of peritoneal carcinomatosis. Patient selection for these aggressive procedures remains a major issue given the substantial morbidity and mortality associated with them.

Follow-Up and Management of Recurrent CRC

The goal of any CRC follow-up regimen should be to detect any recurrences or metachronous lesions that are potentially curable. In a large, multicenter trial, the incidence of second primary CRCs in patients with resected stage II and III lesions was found to be 1.5% at 5 years.¹²⁶ Between 40 and 50% of patients experience relapses after potentially curative resection of CRC. Detection and treatment of recurrent disease before symptom development may improve survival. The time to recurrence is critical in that as many as 80% of recurrences occur within the first 2 years and as many as 90% within the first 4 years. Patterns of recurrence should also be taken into account—for example, the markedly increased risk of local recurrence in rectal cancer patients compared with that in colon cancer patients. Even when recurrent CRC is detected, only a small percentage of patients are candidates for reoperation, and resection in these patients may not improve overall survival. Systemic therapy may improve survival in some patients who have unresectable recurrent lesions.

Various modalities are available for follow-up after surgical treatment of CRC. The history and the physical examination continue to be useful in that a significant percentage of patients

present with symptomatic recurrences. Measurement of serum CEA levels has proved effective in detecting asymptomatic recurrences. More recent studies have shown a survival benefit for CT scanning as part of routine follow-up in patients at a high risk of recurrence. One study that evaluated routine CEA measurement and CT scanning of the chest, abdomen, and pelvis for follow-up of stage II and III CRC demonstrated that both modalities were able to identify asymptomatic patients with resectable disease.¹²⁷ Colonoscopy is valuable for detecting metachronous cancers and polyps. Other studies, such as liver function tests (LFTs), complete blood count (CBC), and chest x-ray, have not been consistently shown to detect asymptomatic resectable recurrences.

Some authorities advocate so-called intensive follow-up. However, this term lacks a standard definition, and such follow-up has not been conclusively shown to be beneficial. In a meta-analysis that compared an intensive follow-up regimen (including history, physical examination, and CEA measurement) with no follow-up, the former detected more candidates for curative re-resection and led to improvements in both overall survival and survival of patients with recurrences.¹²⁸ Three other meta-analyses have been published that assessed the value of intensive follow-up of CRC patients.^{129–131} These meta-analyses included only randomized, controlled trials, and all documented a survival advantage with intensive follow-up. Some caution is required in interpreting these results, however, because the meta-analyses included trials with vastly different follow-up regimens in their baseline and intensive groups.

At present, the ideal follow-up regimen for CRC patients remains to be determined. Intensive follow-up regimens obviously are more costly. Patients with stage I disease are at very low risk for recurrence and therefore do not generally require intensive follow-up.¹³² Patients with stage II and III disease are at significantly higher risk for recurrence and therefore need more specific cancer-related follow-up, but how intensive such a follow-up regimen should be is still a matter of debate.

Several organizations, including the American Society of Clinical Oncology¹³³ and the American Society of Colon and Rectal Surgeons,¹³⁴ have developed algorithms for postoperative surveillance of CRC patients. Their recommendations generally apply to patients with stage II or III disease (and sometimes patients with T2 lesions) who are candidates for resection of recurrent disease. The recommendations vary somewhat among groups, but the following are generally agreed on:

1. Measurement of CEA levels every 2 to 3 months for 2 years, then every 3 to 6 months for 3 years, then annually
2. Clinical examination every 3 to 6 months for 3 years, then annually
3. Colonoscopy perioperatively, then every 3 to 5 years if the patient remains free of polyps and cancer (some guidelines also recommend colonoscopy 1 year after primary therapy)
4. CT of the chest and abdomen for 3 years; pelvic CT should also be done in patients with rectal cancer

Other imaging studies (e.g., PET and chest x-ray) are not routinely recommended, nor are other blood tests (e.g., CBC and LFTs).

A complete review of the treatment of recurrent CRC is beyond the scope of this chapter. The primary aim of postoperative surveillance is the detection of treatable recurrences or metastatic disease. The most common sites of metastasis in CRC patients are the liver and the peritoneal cavity. Surgery is the only potentially curative therapy for recurrent CRC. Only a select group of patients with isolated peritoneal, liver, or lung metastases are candidates for surgical resection. As noted [see Special Considerations, Peritoneal Carcinomatosis, *above*], cytoreductive surgery and HIPEC improve survival in patients with peritoneal carcinomatosis and may lead to long-term survival in a very select group of patients.

Numerous studies have addressed the treatment of patients with isolated liver metastases from CRC. Resection of isolated hepatic metastases has been reported to yield 5-year survival rates higher than 30%, with acceptable surgical morbidity and mortality. Investigators from the Memorial Sloan-Kettering Cancer Center developed a staging system known as the clinical score in an attempt to predict which patients are likely to benefit from aggressive surgical resection.¹³⁵ This system used five factors that were found to be independent predictors of poor outcome: (1) node-positive primary disease, (2) a disease-free interval shorter than 12 months, (3) the presence of more than one hepatic tumor, (4) a maximum hepatic tumor size exceeding 5 cm, and (5) a CEA level higher than 200 ng/mL. Patients who met no more than two of these criteria generally had good outcomes, whereas those who met three or more were recommended for inclusion in adjuvant therapy trials.

PET scanning has also been used to detect occult metastatic disease and thus to aid in the selection of patients for surgical resection. In one series, a 5-year overall survival of 58% was reported after resection of CRC liver metastases in patients screened with PET.¹³⁶ When combined with the clinical risk score, PET was found to be helpful only in patients with a score of 1 or higher.¹³⁷

Modalities for treating unresectable disease confined to the liver include cryotherapy, radiofrequency (RF) ablation, microwave ablation, hepatic artery infusion of chemotherapeutic agents, and hepatic perfusion. Of these, RF ablation is the one most commonly employed. It may be performed via an open approach, percutaneously, or laparoscopically; it may also be combined with resection and with local or systemic chemotherapy. The survival benefit (if any) associated with use of these modalities has not been well established.

Patients with isolated lung metastases from CRC may also benefit from surgical resection. Because there are relatively few of these patients, treatment of such metastases has not been studied as well as treatment of liver metastases. Some series have reported 5-year survival rates higher than 40% after complete resection. Patient selection remains a major issue. Several prognostic factors that may predict poor outcomes have been identified, including (1) a maximum tumor size greater than 3.75 cm, (2) a serum CEA level higher than 5 ng/mL, and (3) pulmonary or mediastinal lymph node involvement.^{138,139} Patients with both pulmonary and hepatic metastases may also be considered for surgical resection.

Pelvic recurrences of rectal cancer present another difficult management issue. These tumors may cause significant pain and disability, and if they are not treated, survival is measured in months. Radiation and chemotherapy provide symptomatic

relief and yield a modest increase in survival. Surgery may provide excellent palliation and is potentially curative in patients who do not have distant metastases.

Multimodality therapy has been advocated as a means of improving the chances of cure. In one study, a 37% 5-year survival rate was reported in patients who underwent multimodality therapy, including resection with negative margins.¹⁴⁰ A subgroup of patients in whom complete resection was impossible underwent intraoperative radiation therapy; the 5-year survival in this subgroup was 21%. Several predictors of poor outcomes were identified, including incomplete resection, multiple points of tumor fixation, and symptomatic pain. In another series, hydronephrosis was associated with the presence of unresectable disease.¹⁴¹ Selection of appropriate

patients for curative surgery remains a major issue in the management of locally recurrent rectal cancer.

Chemotherapy is the mainstay of palliative treatment for patients with CRC and unresectable recurrent or metastatic disease. Combinations of 5-FU and leucovorin with newer agents such as irinotecan, oxaliplatin, and bevacizumab define the current standard. Patients in whom these regimens fail may be considered for treatment with other agents such as cetuximab or other targeted therapies.

Financial Disclosures: None Reported.

16 MOTILITY DISORDERS

Charles H. Knowles, MBBChir, PhD, FRCS, and Robert D. Madoff, MD, FACS, FASCRS

The term “motility disorder” is commonly used to describe conditions in which symptoms are assumed or proven to result from abnormal contractile activity of the gastrointestinal (GI) tract, although from a purist perspective, several thus described disorders also have a sensory component. Surgeons frequently encounter such patients who have challenging problems but in the main no overt structural cause. In what follows, we discuss two of the most common motility disorders, constipation and fecal incontinence, accepting that other rarer disorders where dysmotility is a cardinal feature, for example, achalasia, intestinal pseudo-obstruction, and gastroparesis, may also reach the surgeon’s attention.

Although constipation is infrequently treated surgically, surgeons regularly see patients with constipation in ward and ambulatory settings. It is therefore critical that surgeons have a practical approach to the patient with constipation with respect to diagnosis, investigation, and management. Furthermore, recent pharmacologic and surgical advances are leading to new hope for some patients with disabling chronic symptoms.

Fecal incontinence is an understudied and undertreated condition that can have a dramatic impact on quality of life. Effective treatment of incontinence has a dramatic positive influence on patients’ lives; thus, it is important for surgeons to have both an effective approach to diagnosis and an informed awareness of the various therapeutic options available (including experimental treatments).

Constipation

OVERVIEW AND TAXONOMY

Constipation is a very common digestive complaint in both adults and children, with as much as 20% of the population self-reporting this symptom¹ and with increased reporting over the age of 50.² The definition of the term “constipation” varies greatly between patients and between clinicians, the latter problem emphasized by the confused taxonomy in this field.³ Thus, patients who self-report constipation may refer to defecatory symptoms such as decreased stool frequency, reduced stool volume, altered stool consistency, and difficulty with evacuation or abdominal symptoms such as pain and bloating.⁴ Others may describe even more diverse symptoms, such as general discomfort, nausea, lethargy, and back pain. Given the diversity of potential causes of constipation, the surgeon can be aided by a classification framework [see Table 1]. Using this approach, constipation may broadly be considered primary (often termed idiopathic), encompassing simple and chronic constipation, or secondary, where a defined local structural or systemic cause is evident.

Considering the scope of the chapter (motility disorders), the following text focuses principally on the evaluation and

management of chronic constipation. Although the exact definition of “chronic constipation” has varied in the literature, most would now agree on a simple working definition of more than 6 months of defecatory symptoms that are non- or only partially responsive to standard laxative therapy. This pragmatic definition has been supported by recent large drug trials.⁵ The reader should note that in choosing this approach, several terms introduced as part of the Rome classification of functional GI disorders⁶ have been excluded from this classification. This deliberate exclusion is worthy of some explanation because terms such as “constipation-predominant irritable bowel syndrome (IBS)” and “functional constipation” may be encountered by surgeons (particularly when communicating with internal medical colleagues). In brief, a succession of consensus committees (meeting in Rome over the past 20 years) have attempted to carefully define various diagnoses (now actually 44 entities from mouth to anus) based on specific combinations of symptoms. For instance, a patient meeting a list of criteria for defecatory symptoms and abdominal pain could be defined as having constipation-predominant IBS. Such criteria may be useful for research-related activity, for example, drug trials (although this is itself debatable), but have little practical value in the diagnosis or management of patients with chronic constipation. Furthermore, there is very poor epidemiologic concordance between the Rome definitions, self-reported constipation, and constipation as defined by physiologic measurement.^{7–9}

CLINICAL EVALUATION

History

Figure 1 is an algorithm for the workup and management of constipation. When a patient presents with a complaint of constipation, a thorough history of the presenting illness is essential. Probably first and foremost is the determination of whether constipation represents a new complaint, that is, one that may be indicative of a change in bowel habit. The patient should be asked specifically about the frequency and consistency of bowel movements and the progress of such changes over time (as well as other alarming symptoms, such as rectal bleeding, anorexia, and weight loss). On this basis, with additional information regarding family history, previous colon cancer screening, and other GI investigations, an informed decision can be made as to whether structural intraluminal investigation of the colon is required. Other organic causes of constipation may be deduced by appropriate history taking and biochemical investigation. With the exclusion of treatable secondary causes, if the history is short and multiple previous therapies have not already been tried, then the patient may be first considered to have “simple” constipation that can be managed with reassurance and lifestyle advice (fiber, fluids, and exercise). However, some patients will have attended many

Table 1 Classification System for Constipation

Secondary constipation
Gastrointestinal causes
Colorectal
Malignant neoplasms, inflammatory strictures, diverticular disease
Megacolon or megarectum
Idiopathic
Hirschsprung disease
Neurologic
Chagas disease
Anorectal
Anal atresia or malformation
Hereditary internal anal sphincter hypertrophy
Anal stenosis
Extragastrintestinal causes
Metabolic and endocrine
Hypothyroidism, diabetes, hypercalcemia, chronic renal failure, pregnancy
Neurologic
Degenerative CNS diseases
Spinal lesions
Damage to sacral parasympathetic nerves
Autonomic neuropathy
Drugs
Opioids
Anticholinergics
Antidepressants
Anticonvulsants
Psychological
Severe endogenous depression
Eating disorders
Other
Scleroderma, Chagas disease, amyloidosis
Primary (idiopathic) constipation
Simple (reversible) constipation
Lifestyle
Exercise, mobility
Diet
Fiber, hydration
Chronic idiopathic constipation*
Evacuation disorder (ED) (40%)
Dynamic structural abnormalities, e.g., rectocele, intussusception
Pelvic floor dyssynergia
Poor defecatory effort
Slow-transit constipation (STC) (10%)
Colonic inertia
Both ED and STC (35%)
No physiologic abnormality evident (15%)
Normal transit constipation†

CNS = central nervous system.

*Approximate percentages have been included based on the experience of over 1,000 consecutive patients at the Royal London Hospital.

†This rather confusing term has become popular in the literature. Note that this group does not equate with “constipation-predominant irritable bowel syndrome.”⁹⁹

physicians already, with various therapies already exhausted. In such patients, a workup for chronic constipation may be indicated.

In reality, it is usually evident whether a patient with chronic symptoms is one in whom a secondary cause should be sought or one in whom the focus should shift to the investigation and management of idiopathic constipation. This decision is helped by overwhelming epidemiologic evidence that patients with chronic idiopathic constipation are usually female (90% or more)^{10,11} and often have symptoms from early childhood or puberty (at least 50%)¹¹ or problems that

start after pelvic surgery, for example, hysterectomy or childbirth.¹² Thus, the history should ascertain the duration and mode of onset of symptoms. In relation to onset, it may sometimes be necessary to tactfully seek a history of physical or sexual abuse because this can sometimes precipitate defecatory problems.¹³ A history of other family members with either severe constipation or Hirschsprung disease should also be sought. Furthermore, it is helpful at this stage to systematically document the spectrum of symptoms that in the patient's mind constitute a problem because this has some bearing on treatment decisions and subsequent monitoring of effectiveness. Several questions form detailed scoring systems to systematically facilitate this in a research context, for example, Cleveland Clinic Constipation¹⁴ and Knowles-Eccersley-Scott-Symptom¹⁵ scores, but in routine practice, it is sufficient to list in the patient record the presence or absence (with some indication of degree) of each symptom. We specifically ask about the following, with and without laxatives (if relevant):

- Frequency of spontaneous or assisted bowel opening
- Painful defecation
- Stool consistency
- Digitation (vaginal or anal)
- Straining
- Abdominal pain
- Incomplete evacuation
- Bloating
- Unsuccessful evacuation with or without toilet revisiting

The remaining history should document prescribed and self-administered laxatives (and the therapeutic benefit thereof) and gain an impression of the quality of diet with respect to fiber and fluid intake.

Physical Examination

During the physical examination, it is important to make a quick assessment of the patient's nutritional status. In general, patients with idiopathic constipation should not appear malnourished; the appearance of malnutrition should prompt a more extensive search for a secondary cause, including occult carcinoma, more widespread dysmotility syndromes such as chronic intestinal pseudo-obstruction, and eating disorders. An abdominal examination should be conducted to look for scars, any significant abdominal distention, tenderness, or masses. Bloating is a common and expected finding with idiopathic constipation, but significant distention, tenderness, or masses should prompt a full investigation.

All patients presenting with constipation should undergo a rectal examination. The perineum and anus should be examined for evidence of fecal incontinence that may indicate impaction and overflow. Fecal incontinence and chronic constipation coexist to some degree in 40% of patients¹⁶; marked soiling of the underwear is especially associated with the rarer diagnosis of megarectum. Scarring, for example, from an episiotomy, sentinel pile formation secondary to underlying fissure, external hemorrhoids, or prolapse may also be present. The degree of perineal descent on straining, which is indicative of pelvic floor weakness, should also be determined. A digital rectal examination should be done to diagnose impaction, gain a rough measure of anal tone at rest and on

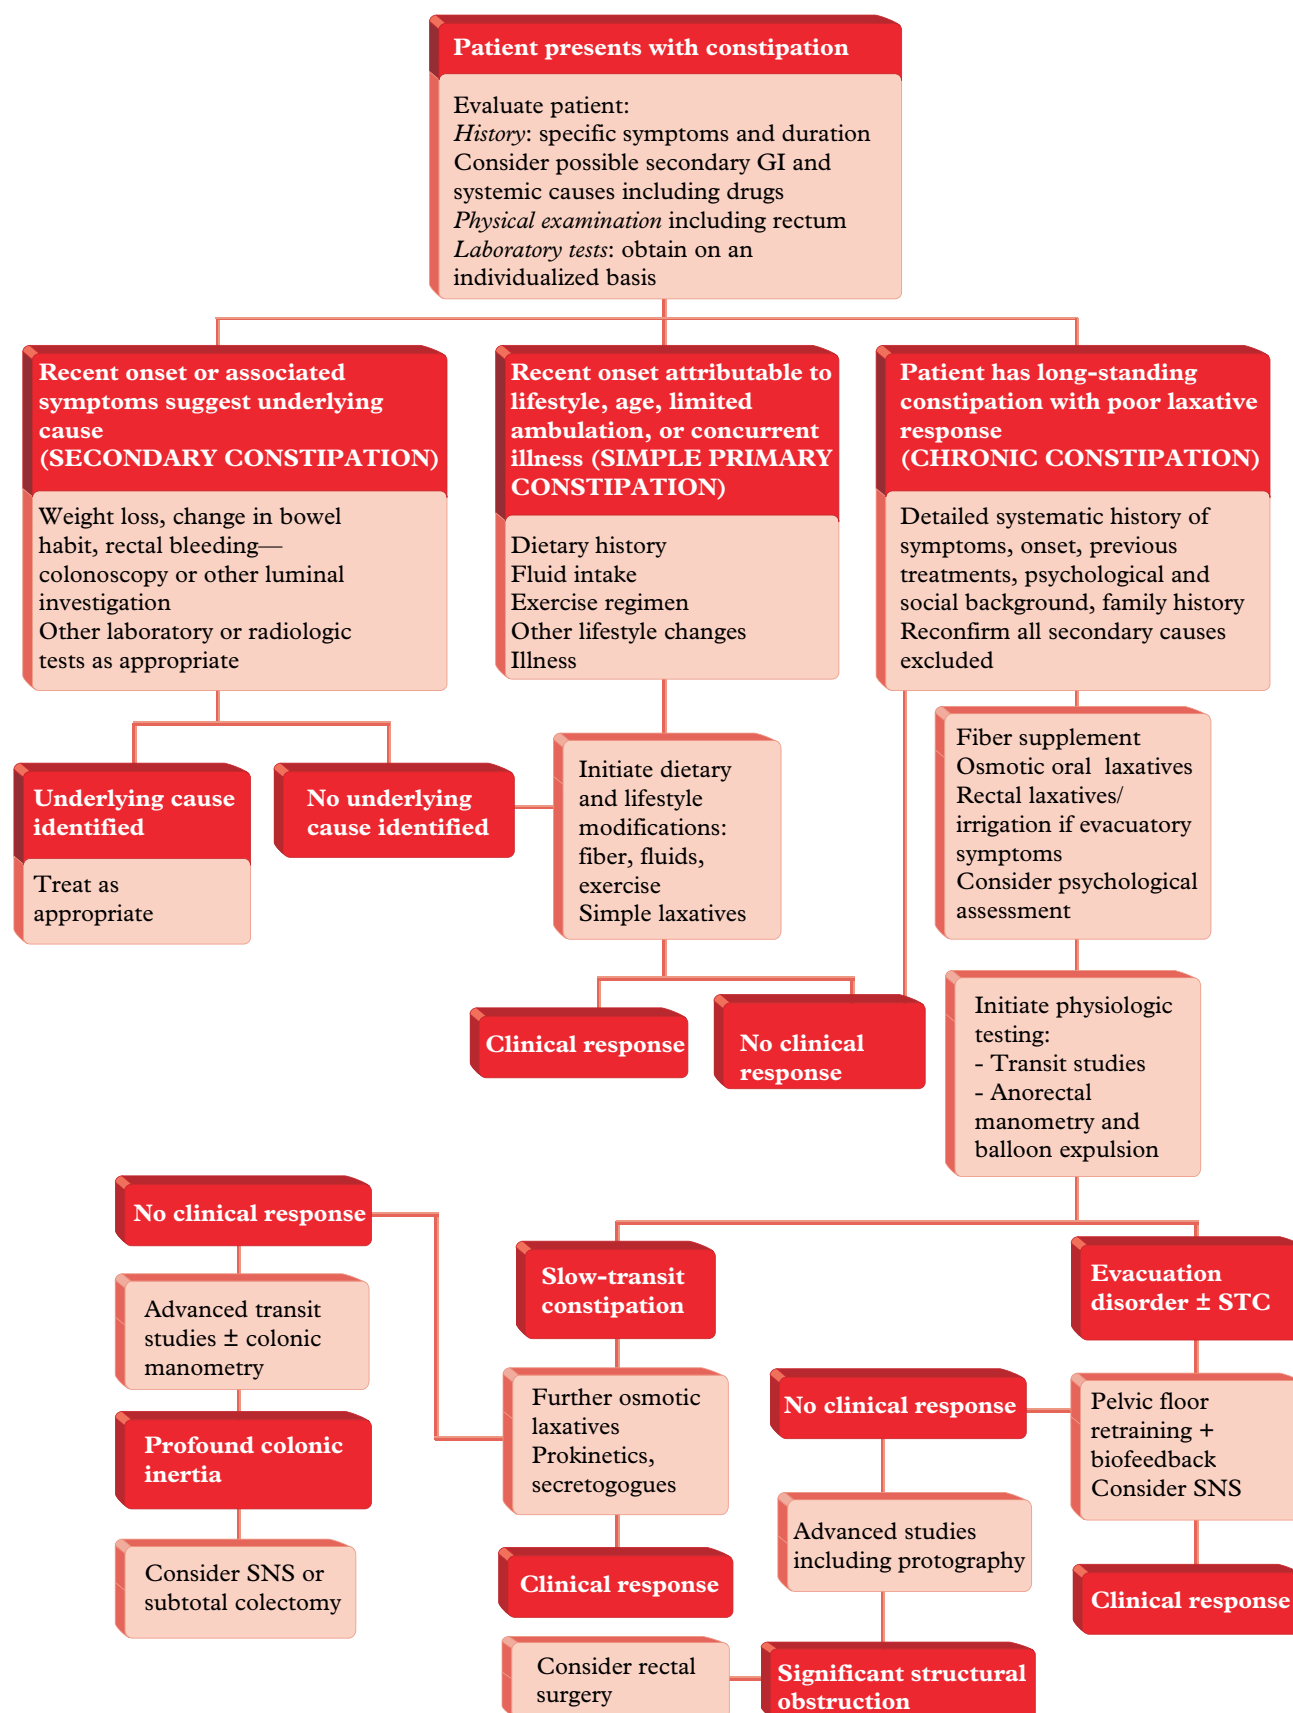

Figure 1 Algorithm outlining the workup and management of constipation. GI = gastrointestinal; SNS = sacral nerve stimulation; STC = slow-transit constipation.

squeezing, and ascertain obvious sphincter defects. Furthermore, an effort should be made to look for any anterior defect in the rectovaginal septum leading to a rectocele (your digit will appear within a pouch visible in the posterior vagina). On removing the digit from the anus, it is sometimes possible to appreciate the presence of an intra-anal intussusception or mucosal prolapse that “drags” out with the examining digit.¹⁷ It is unlikely that a digital examination can give useful information on paradoxical puborectalis contraction (dyssynergia), although the experienced examiner can sometimes have the impression of pelvic floor contraction during straining. The finding of a rectal mass warrants further investigation. Anoscopy and proctoscopy should be performed if there is any history of rectal bleeding and may indicate fissure or internal piles.

INVESTIGATIVE STUDIES

In general, diagnostic studies can be divided into those conducted to rule out an underlying cause of secondary constipation (e.g., partially obstructing colon cancer, metabolic or endocrine cause) and those used to diagnose specific anorectal or colonic physiologic abnormalities associated with chronic idiopathic constipation.

Investigations for Secondary Causes of Chronic Constipation

Although the findings from the history or physical examination may indicate a possible secondary cause of constipation, making further investigation mandatory (e.g., for a change in bowel habit), it is also typical practice in patients with chronic constipation to exclude certain secondary causes by investigation even though the diagnostic utility of such investigations is acknowledged to be low (the most common undiagnosed systemic disease is hypothyroidism). Thus, serum calcium concentrations, thyroid function tests, hemoglobin concentrations, glucose levels, serum electrolyte levels, and creatinine concentrations are usually performed. The approach taken to structural investigation of the colon when patients have no suspected intraluminal pathology varies internationally and on the basis of available resources. In the United States, for patients older than 50 years, the baseline risk of colorectal cancer is sufficiently high that screening colonoscopy is recommended even in the absence of alarming symptoms. These older patients should therefore undergo routine colonoscopy, and many authors recommend that patients younger than 50 years undergo routine flexible sigmoidoscopy. Routine biopsies have no benefit however. In Europe, this approach is being increasingly adopted. At some stage, it is worth assessing the rectum and colon so that subsequent management (which may be protracted or unsuccessful) can start with a baseline of reassurance that no organic disease is present. Barium enema can still be a useful investigation in this instance because it yields more information on colonic diameter (for rarer cases of megacolon) and the distribution and severity of diverticular disease, which may coexist and be responsible in part for symptomatology.

Investigations for Primary (Idiopathic) Chronic Constipation

In patients with chronic constipation in whom basic laxatives have failed, further specialist investigative tests are usually warranted. These tests are conducted to provide information on the underlying pathophysiologic abnormalities

of the colon and/or anorectum on the basis that the results will guide further management. Most opinion leaders agree that such tests are of value, although opinions differ on how rigorous such investigations should be and when in the algorithm they should be performed. Although there is a general lack of evidence that targeted management strategies are superior to empirical stepwise treatments in earlier pharmacologic and behavioral interventions, it is at least generally agreed that such tests are mandatory if surgery is considered.^{18,19} Finally, it should be noted that all are dependent on adequate normative data (sex and age relevant), the expertise of the investigator, and correct interpretation in the context of the clinical information.

These investigations also vary in their availability and complexity internationally. Table 2 lists standard and advanced tests. An additional, often-neglected investigation that can be performed and reviewed immediately in the ambulatory setting is plain abdominal radiography. This is particularly useful as a screening tool for determining whether the symptoms volunteered by patients correlate with a colon loaded with feces and may be shown to the patient to aid discussion.

The mainstay for the rapid evaluation of colonic transit is the radiopaque marker study. Although variations in technique exist in terms of the number of markers, the interval to radiography and definition of slow transit (in the United Kingdom, typically 50 markers, 100 hours, and > 20% remaining),²⁰ the basic premise is that a number of markers (small pieces of plastic tubing, prepackaged in gelatin capsules) are ingested, and an abdominal x-ray (which includes the pelvis) is taken at an interval. The patient abstains from laxatives for the duration of the study. In patients with significant numbers of retained markers (based on control data), slow transit is diagnosed [see Figure 2a]. Alternatively, transit can be measured by radioscintigraphy^{21,22} [see Figure 2b] or a wireless motility capsule²³ [see Figure 2c]. These techniques are valid but not yet widely available. On the basis of radiopaque marker studies, approximately 40% of patients with chronic constipation will have delayed transit.^{18,24} Abnormal transit may be demonstrated either throughout the colon or within a limited portion thereof (most commonly, the sigmoid and the rectum).²¹ In the latter, it is unresolved whether such markers represent a primary disturbance of rectosigmoid motility or are retained secondary to a primary problem of evacuation,²⁵ which is also present in more than half of the slow-transit constipation (STC) group.

Figure 3 schematically shows the normal process of defecation [see Figure 3, a–c] and the three most common causes of evacuation disorder (ED) [see Figure 3, d–f]. Pelvic floor studies are valuable for determining the presence and pathophysiology of ED and are best conducted in a pelvic floor laboratory with a specific interest in anorectal function. The balloon expulsion test can be performed in the office as an initial screening measure. A balloon filled with 50 mL of water is attached to tubing and placed in the rectum. Patients with an evacuation disorder are then defined as those who cannot expel the balloon from the rectum in 1 minute while sitting on a commode. It should be kept in mind, however, that as many as 12% of patients with normal pelvic floor function will have difficulty with balloon expulsion in this setting.²⁴ Furthermore, the literature has become confused by

Measure	Standard	Advanced
Colonic transit	Radiopaque marker study	Colonic isotope scintigraphy
Colonic contractile activity	—	Colonic manometry
Anal sphincter contraction	Anal manometry (water perfused)	High resolution anal manometry
Rectal sensory testing and distention	Simple balloon distention	Rectal barostat
Rectoanal inhibitory reflex	Balloon and anal manometry	Integrated barostat-manometry
Rectal expulsion (defecation)	Balloon expulsion test	Integrated proctography
	Evacuation proctography	Integrated proctography

Figure 2 (a) Slow colonic transit: radiopaque marker study—all markers remain in the proximal colon. (b) ^{111}In isotope scintigraphy showing normal progression of isotope in a healthy control and generalized slow-transit delay. (c) SmartPill study measuring whole gut transit: progression of the capsule is determined by changes in pH and impedance. This patient has a normal colonic transit of less than 48 hours. CTT = colonic transit time; GRT = gastric retention time, SBT = small bowel transit time, WGTT = whole gut transit time.

Figure 3 Schematic representation of normal defecation and common causes of evacuation disorder: (a) pelvic floor muscles at rest with preservation of the normal anorectal angle; (b) contraction of abdominal muscles and relaxation of puborectalis and external sphincter muscles leading to straightening of the anorectal angle; (c) relaxation of internal sphincter and evacuation of stool with rectal contraction; (d) puborectalis dyssynergia: the puborectalis sling has paradoxically shortened during straining, leading to exaggeration of the anorectal angle and obstruction of fecal progression; (e) rectocele: feces is pushed during straining into the vagina, which then retains feces at defecation, leading to incomplete evacuation; and (f) rectal intussusception: the rectum has internally prolapsed, leading to obstructed defecation during straining.

the assumption that this test is automatically diagnostic of an entity known as puborectalis dyssynergia (also sometimes termed pelvic floor dyssynergia, paradoxical puborectalis contraction syndrome, or “anismus”).^{24,26} The nonspecialist reader need not become too embroiled in the semantics of this diagnosis, but it suffices to mention that the balloon expulsion test can de facto determine only the ability to expel, not the underlying mechanism leading to failed expulsion. Thus, in patients who remain refractory to therapy, more advanced tests of evacuation may be indicated. Many specialist centers use defecography (also known as evacuation proctography) to evaluate evacuation. Barium paste is formulated so as to simulate a fecal bolus and is placed in the rectum. The patient is asked to defecate on a radiolucent commode, and the event is recorded with fluoroscopy. During normal defecation, the puborectalis and the anal sphincter muscles relax, and the rectum assumes a more

vertical position with respect to the anal canal, facilitating evacuation of stool. In a patient with puborectalis dyssynergia, defecography typically demonstrates failure to open the anorectal angle and persistence of the puborectalis impression during defecation, as well as failure to empty completely.²⁷ Other important findings that may also be noted include rectocele, internal intussusception, and rectal prolapse. There are pros and cons to both approaches, including pelvic radiation dose for defecography (often in young women).

In addition to the balloon expulsion test, pelvic floor evaluation generally involves manometry. Anal canal pressures are recorded at 1 cm intervals throughout the anal canal during rest and squeeze. A balloon is then expanded within the distal rectum and to assess reflexive relaxation of the internal sphincter to rectal distention. The presence of this reflex rules out adult Hirschsprung disease (a very rare cause of

constipation). In many centers, the ability of the patient to sense rectal balloon distention is also determined because loss of the urge to defecate may be caused by blunted rectal sensation (rectal hyposensation).²⁸ In patients with suspected puborectalis dyssynergia, manometry can be employed during straining to demonstrate either failure to relax to enable expulsion or paradoxical contraction.^{24,29} Similar findings during straining can also (if required) be documented by means of electromyography (EMG) with a sponge electrode in the anal canal.²⁹

MANAGEMENT

Chronic Idiopathic Constipation

Figure 1 illustrates that many treatments can be initiated without prior physiologic testing. Following detailed history taking, the patient's past drug use will be documented and can guide further therapy. The evidence base for an exact protocol of laxative use is poor,³⁰ with only polyethylene glycol (PEG)-based osmotic laxatives having been rigorously subjected to trials in the modern randomized, controlled trial age.³¹ Nevertheless, stool softeners (e.g., docusate), stimulant laxatives (e.g., senna and bisacodyl), and osmotic laxatives (e.g., PEG, lactulose, and magnesium salts) may be used alone or in combination with good effect. Bulking agents often cause further abdominal pain and bloating in patients with chronic constipation. Furthermore, attempts to prescribe such products (such as encouraging further dietary fiber intake, exercise, and fluids) will in general be met with hostility by patients who have exhausted such measures many years before and lead to an erosion of trust. In the absence of evidence, we make the following practical suggestions:

- Reassure the patient that modern laxatives do not damage the bowel.
- Try to stop all current laxatives, that is, do something definite (this is referred to as “switching” in the psychiatric literature).
- Consider use of rectal laxatives ($\pm$ oral purgatives) in patients with defecatory symptoms; these have often not been tried.
- Consider laxative dose titration (e.g., magnesium salts).
- Prescribe and monitor the chosen therapy at a fixed interval, for example, 3 months.
- Warn of side effects but emphasize the need for compliance.
- Rotate the laxative type at regular intervals to avoid tolerance.

Other drugs acting on secretion and motility are discussed under Slow-Transit Constipation (see below) but may equally be employed for patients with chronic constipation that has not been further physiologically defined. Similarly, there is some evidence that behavioral treatments may benefit all patients with chronic constipation³² rather than just those with pelvic floor dyssynergia. However, for clarity and better understanding, further discussion of these has been separated by subtypes of chronic constipation.

Slow-Transit Constipation

Medical treatment Patients with STC are primarily treated by addressing the transit disturbance of the colon

(although ED commonly coexists). In this group, the mainstay of therapy is the use of osmotic and stimulant laxatives (alone or in combination) to effect changes in transit^{33,34} with benefit proven in controlled trials.³⁵ A theoretical problem with all classic laxative therapies is their bioavailability in the colon. All require transport to the colon for site of action, and some require metabolism via the enteral flora to produce active products, for example, hydrolysis of stimulant laxatives. Furthermore, laxatives are often poorly tolerated because of pain (mainly stimulant) or unpredictable diarrhea with or without incontinence (mainly osmotic). Given the burden of disease, much investment has been made to find newer classes of drug to treat chronic constipation. To date, two classes of drug are being developed: colonic prokinetics, based on activity at serotonin receptor subtype 4 (5-HT₄ agonists), and intestinal secretagogues.

The main development in the 5-HT₄ agonist class is prucalopride. This drug has much greater selectivity to the 5-HT₄ receptor than the now withdrawn 5-HT₄ agonists such as tegaserod and cisapride. In particular, it has no proven effect on QTc interval caused by activation of the cardiac conducting system channels that led to arrhythmias with less selective drugs. Prucalopride has been the subject of three rigorously conducted phase III pivotal trials with pooled data available on over 2,000 patients.⁵ Abundant cross-species data (including humans) show that prucalopride leads to increases in propagated colonic contractile activity, leading to coordinated mass movements and spontaneous defecation.³⁶ It has an acceptable side-effect profile and is currently licensed in Europe for women with chronic constipation; it has some effect in approximately 50% of patients.⁵ In particular, it has a significant advantage over laxatives in terms of reducing rather than increasing abdominal pain and bloating.

Two drugs, lubiprostone (a chloride channel activator) and linaclotide (a guanylate cyclase C receptor activator), accelerate colonic transit in humans by mediating luminal secretion. Lubiprostone has a phase III portfolio and is approved by the Food and Drug Administration (FDA) for chronic constipation but is reported to cause problematic nausea in approximately 20% of patients.³⁷ Linaclotide is at an earlier developmental stage and has proved effective in phase II trials.³⁸

Surgical treatment Until very recently, colonic excision was the only popularized form of surgery to address STC. It is a fact that colectomy has a “finality” that separates it not only from medical treatments but also from most other invasive interventions for constipation. The results of colectomy have been extensively reviewed previously,^{19,39} with overall success rates varying between 40 and 100%. It is probable that colectomy peaked in popularity in the mid-1990s but has seen a gradual decline in application since publications of more modest longer-term results became available and the potential for serious complications and poor functional outcomes was realized.⁴⁰ Nevertheless, most would agree that colectomy continues to have a limited role as a treatment option for highly selected patients with proven STC (probably < 5% chronic constipation) who have failed all nonsurgical interventions and in whom symptoms are sufficiently severe to contemplate major surgery. Such surgery should be undertaken only in specialized centers where the techniques

required for selection are available. Subtotal colectomy with ileorectal anastomosis has the best results, leading to a median stool frequency of three (range one to five) per day. Unfortunately, surgery may not satisfactorily alleviate other symptoms (e.g., abdominal discomfort or bloating),⁴¹ and patients should be made aware of this possibility before operation. Overall, the majority of well-selected patients are satisfied with the results of surgical treatment^{42,43}; however, long-term postoperative complications, particularly small bowel obstruction, are common. In addition, patients may manifest symptoms of a more global GI dysmotility disorder in the long term.

The role of sacral nerve stimulation (SNS) is being critically evaluated following the very recent publication of a multicenter European trial showing the beneficial effect of SNS in 39 of 62 (63%) chronic constipation patients who predominantly had STC⁴⁴ and other studies with less encouraging results.⁴⁵ Mechanistically, SNS increases pancolonic anterograde propagated sequences in patients with STC.⁴⁶ Controlled studies are required particularly because SNS is not cheap. However, the attraction of this minimally invasive treatment and possibility of pretesting patients prior to stimulator implantation make it a promising tool for patients who might otherwise progress to colectomy.³⁹

A stoma may be used as a definitive procedure, as a guide to further treatment, or as salvage from previously failed or complicated surgical intervention. There are few published data to support an evidence-based use; however, an ileostomy may be employed as a guide to colectomy, with subsequent resection avoided if the ileostomy output is unsatisfactorily high or symptoms such as pain and bloating are untouched by diversion.⁴⁷ As a definitive procedure, both colostomy and ileostomy have been described for a diversity of disorders characterized by constipation, including spinal cord injury, megacolon, and ED. There is little evidence in adults to guide the choice of ileostomy or colostomy⁴⁸; however, some report high complication rates of ileostomy,⁴⁹ and STC may be unsatisfactorily treated by colostomy.

The Malone anterograde continent enema technique may also be an option for refractory STC but has been employed more frequently in patients with severe ED [see Evacuation Disorder, *below*].

Evacuation Disorder

Patients with evidence of ED can be subdivided broadly into those with an obvious structural cause, such as a large rectocele or intussusception, and those in whom no such cause is found but in whom defecation is still ineffective. Depending on the definition and methods used to diagnose, 20 to 75% of the latter will be found to have puborectalis dyssynergia^{24,29}—the term used to describe paradoxical or noncontraction of the pelvic floor during straining. The evidence base for ED management is fraught with semantic differences; however, a few key management strategies have general agreement:

- All patients may benefit from nurse-led bowel retraining and rectal laxatives and/or anal irrigation.
- Patients with large rectoceles in whom clinical (the patient can successfully effect evacuation by digital pressure in the vagina) and radiologic findings concur should have these

repaired by one of the numerous transvaginal, transperineal, or transanal approaches.^{50,51} However, the optimal operation for rectocele remains a matter of debate.

- Patients with proven or suspected puborectalis dyssynergia should undergo behavioral retraining incorporating biofeedback.

Behavioral therapy The predominant behavioral treatment is biofeedback. This (usually nurse-led) therapy retrains the patient to appropriately contract her abdominal and relax her pelvic floor muscles during defecation, with the patient receiving feedback of anal and pelvic floor muscle activity as recorded by surface EMG, anal pressure sensors, or digital examination by the therapist. Several controlled trials and meta-analyses provide data on biofeedback outcomes in comparison with sham or alternative treatments.¹⁸ Opinions vary on which patient groups most benefit, with some favorable³² and some unfavorable⁵² results for patients with STC. However, most would agree that this treatment is best targeted at those with ED, particularly those with proven puborectalis dyssynergia. The results range from approximately 70 to 90% success rates in adults with ED,^{52–54} with a recent meta-analysis of three randomized, controlled trials giving an odds ratio of success over placebo of 3.7 (95% CI 2.1 to 6.3).⁵⁵ Training may have to be reinforced at intervals but is generally sustained in the longer term.

Anorectal surgery The repair of large rectoceles has been noted above and can be performed by urogynecologists who are more familiar with approaches that avoid the rectal lumen.⁵¹ Much more contentious are the numerous surgical approaches for smaller rectoceles, intussuscepta, or both (these frequently coexist). An “industry” of operations that either hitch, reinforce, or excise rectal tissue have been described.³⁹ All are beset with the following problems in relation to the treatment of ED:

1. Anatomic abnormalities such as rectocele and intussusception are detectable in significant proportions (at least 40%) of asymptomatic subjects.⁵⁶
2. Such abnormalities often belie a complex multifactorial problem with several contributing etiologies that cannot be corrected by surgery alone.^{57,58}
3. Promising early success in case series (e.g., 90%⁵⁹) often becomes less encouraging in the longer term (approximately 50%).^{60,61}
4. There are no bona fide data from randomized, controlled trials for any procedure.³⁹
5. Although many procedures have generally low morbidity, none are without the risk of serious complications in at least a minority of patients.⁶²

Two procedures require specific mention as a result of their current popularity.

Laparoscopic ventral rectopexy was first described for full-thickness rectal prolapse⁶³ but has been applied to the treatment of intussusception since 2008.⁶⁴ The rectum is mobilized anteriorly to the pelvic floor and a mesh is sutured to the ventral rectum, posterior vagina, and vaginal fornix and secured to the sacral promontory. Excellent short-term results have recently been published for this procedure⁶⁵; however,

longer-term data are lacking, and complications have also been recorded.⁶⁴

With the advent of suitable staple devices and widespread introduction of stapled hemorrhoidopexy, a currently popularized intervention is that of stapled transanal rectal resection (STARR), in which the internally prolapsed rectum is excised with the aim of improving anatomy and function.⁶² STARR is applicable for both intussusception and small rectoceles; however, controversial results are reported, ranging between 90% success in the short term to 55% persistence of symptoms after 18 months.⁶⁶ Furthermore, reported complications of STARR include bleeding, fecal incontinence, excruciating anal pain, rectal diverticulum, rectovaginal fistulas, and even fatal pelvic sepsis. Painful defecation, possibly attributable to retained staples in the puborectalis muscle, affects 20% of patients 1 year postsurgery, and chronic proctalgia requires reintervention in approximately one third of patients.⁶² This “trade-off” between satisfaction in the majority and serious complications in the minority is one that might be deemed acceptable by some surgeons but not by others (including the authors).

Other surgical approaches Anterograde enema can be considered an alternative to stoma in patients with severe ED when conservative methods with or without anorectal procedures have failed or are contraindicated.⁶⁷ In patients with previous appendectomy or in whom the appendix cannot be satisfactorily employed, cecostomy may be effected using a percutaneously placed Chait tube or surgically by more complex techniques.⁶⁸ In general, success rates have been lower in adults^{67,68} than in children: approximately 50 versus 80%. In the long term, complications such as stomal stenosis and leakage, or failure to effectively treat symptoms commonly (> 50% at 3 years), lead to revision, reversal, or conversion to stoma.⁶⁸

Currently, there are few specific data on the efficacy of SNS for ED. Indeed, although numerous data exist on functional changes in anorectal physiologic functions with SNS,⁶⁹ its effect on evacuation has remained relatively unstudied. There is, however, a good rationale for its use in such patients based on the fecal incontinence literature [*see Fecal Incontinence, below*], and studies are ongoing.

Fecal Incontinence

OVERVIEW AND TAXONOMY

Fecal incontinence may be defined as the involuntary loss of rectal contents through the anal canal. It is a relatively common condition, occurring in an estimated 2.2% of persons in the United States.⁷⁰ Its exact prevalence is unknown, however, and appears to vary with the population being studied. For example, nearly 50% of nursing home patients are incontinent to stool.⁷⁰ Fecal incontinence is often treated inadequately, either because of underreporting of symptoms to the physician⁷¹ or because of ignorance or disinterest on the physician's part.

Fecal incontinence makes a significant contribution to medical morbidity (e.g., urinary tract infections and decubitus ulcers), but its main impact is on quality of life. Affected patients experience embarrassment and shame, and

many dramatically alter their lifestyle in an effort to avoid accidents.

Normal continence depends on a chain of interdependent processes, and disruption of any of the links in the chain can lead to incontinence. Frequently, a combination of factors is responsible for the incontinence.

Individuals must have adequate mental function to care about continence and must have an intact neurologic arc from the brain to the anal sphincter to maintain normal continence. A wide array of neurologic disorders can lead to incontinence, including dementia, strokes, spinal cord injury, multiple sclerosis, and diabetic autonomic neuropathy. So-called idiopathic fecal incontinence is caused by pelvic floor denervation resulting from traction injury to the pudendal nerves.⁷² The injury is usually caused by straining and consequent pelvic floor descent during obstetric delivery or by chronic straining at stool.

Conditions characterized by abnormal GI function, especially diarrheal states, can cause or exacerbate incontinence. Common causative conditions include infectious diarrhea and inflammatory bowel disease. Diarrhea-predominant IBS can contribute to incontinence in patients with other associated disorders. Fecal impaction is an important cause of incontinence, particularly in older and institutionalized populations.⁷³

Abnormalities of the pelvic floor are frequent causes of incontinence. Some such abnormalities are congenital malformations (e.g., imperforate anus, rectal agenesis, and cloacal defect). More often, abnormalities are attributable to acquired sphincter injuries. Common causes of sphincter injury include obstetric injury, pelvic fracture, and traumatic impalement [*see Figure 4*]. One of the most frequent causes is an anorectal procedure, such as fistulotomy,⁷⁴ sphincterotomy,⁷⁵ or anal dilatation.⁷⁶ Sphincter-sparing rectal resections can also lead to incontinence as a consequence of both the loss of the normal rectal reservoir and the sphincter injury caused by transanal introduction of intraluminal staplers.

CLINICAL EVALUATION

History

A careful patient history and a directed physical examination are the most important elements of clinical evaluation for a patient with fecal incontinence [*see Figure 5*]. The patient should be asked about the onset and nature of the incontinence (e.g., whether the stool is liquid or solid and whether flatus is present), any associated changes in stool consistency or bowel habits, and the frequency of incontinence. A pertinent but thorough medical, surgical, and obstetric history should be obtained, and any underlying contributory conditions (e.g., colitis) should be treated. The impact of the incontinence on the patient's quality of life should be assessed, at least qualitatively.

Physical Examination

The physical examination should focus primarily on the perineum. Seepage and secondary perineal skin breakdown should be noted, as should scars from previous surgical treatment or trauma. Perineal body deformity is an important sign of obstetric injury, and gaping of the anus with traction on the buttocks is suggestive of rectal prolapse. When prolapse

Figure 4 Shown is an obstetric sphincter injury.

is suspected but not evident, the patient should be asked to strain while seated on a commode. Digital rectal examination is useful for detecting low rectal tumors and fecal impaction; it also provides a qualitative assessment of both resting sphincter tone and voluntary squeeze pressure.

INVESTIGATIVE STUDIES

Endoscopy should be performed on all incontinent patients to exclude a neoplastic or inflammatory condition. In most cases, flexible sigmoidoscopy is adequate, but if the patient has unexplained diarrhea, bleeding, or changed bowel habits, a complete colonoscopy should be performed.

Anorectal testing is indicated for most patients with significant incontinence, particularly if operative treatment is being considered. The most important test is endoanal ultrasonography (EAUS), which yields a highly accurate assessment of sphincter integrity [see Figure 6].⁷⁷ At some centers, magnetic resonance imaging (MRI) has become the test of choice for evaluating the pelvic floor. Anal manometry

provides a quantitative assessment of resting and squeeze anal pressures, which serve as indicators of internal anal sphincter function and external anal sphincter function, respectively. EMG may be used to diagnose neuropathic injury of the pelvic floor. Although concentric-needle EMG is the most accurate technique, most centers employ a glove-mounted intra-anal electrode to measure pudendal nerve conduction time (i.e., pudendal nerve terminal motor latency [PNTML]). The practical utility of PNTML testing is debatable, however, and opinions vary regarding the test's ability to predict successful outcomes after anal sphincter repair.^{78,79} When the cause of incontinence is uncertain, dynamic imaging of the pelvic floor with defecography or MRI may reveal an occult pathologic state (e.g., occult rectal prolapse).

MANAGEMENT

Conservative Management

Minor incontinence should be treated first with conservative measures. Dietary changes (e.g., avoidance of foods that cause diarrhea or urgency), fiber supplementation, and bowel habit training are helpful for most patients, as is regular use of loperamide. Perianal skin excoriation should be treated with a barrier cream, and seepage may be controlled either with placement of a small cotton wick at the anal orifice or, occasionally, with rectal washouts.

Biofeedback

Biofeedback appears to be an effective therapy for fecal incontinence in a high percentage of patients.^{80,81} It is an inherently attractive approach because it is simple, painless, and risk-free. However, the biofeedback literature consists mostly of small, uncontrolled, retrospective studies, and its specific efficacy has been questioned. A randomized, controlled trial from 2003 found that biofeedback had no advantages over standardized medical and nursing care (i.e., advice) or advice plus sphincter exercises.⁸² In contrast, a more recent randomized trial showed that manometric biofeedback with pelvic floor exercises was more effective than pelvic floor exercises alone in treating fecal incontinence that had failed conservative management.⁸³

Sphincteroplasty

Anal sphincter repair is the most widely accepted operation for fecal incontinence [see Figure 7]. In acute situations (e.g., when an obstetric sphincter injury is recognized), immediate direct repair is generally recommended. Unfortunately, as many as 75% of women have persistent external anal sphincter defects after primary repair, and about 60% have some degree of incontinence.⁸⁴ If immediate repair is not attempted, surgical treatment should be delayed at least 3 to 6 months to permit resolution of local tissue inflammation and edema.

For incontinent patients with established sphincter defects, overlapping sphincteroplasty is the procedure of choice. Complete bowel preparation is carried out before the procedure, and prophylactic antibiotics are administered.

Operative technique *Step 1:* initial dissection The patient is placed in the prone jackknife position, with the buttocks taped apart and a large roll beneath the hips. A

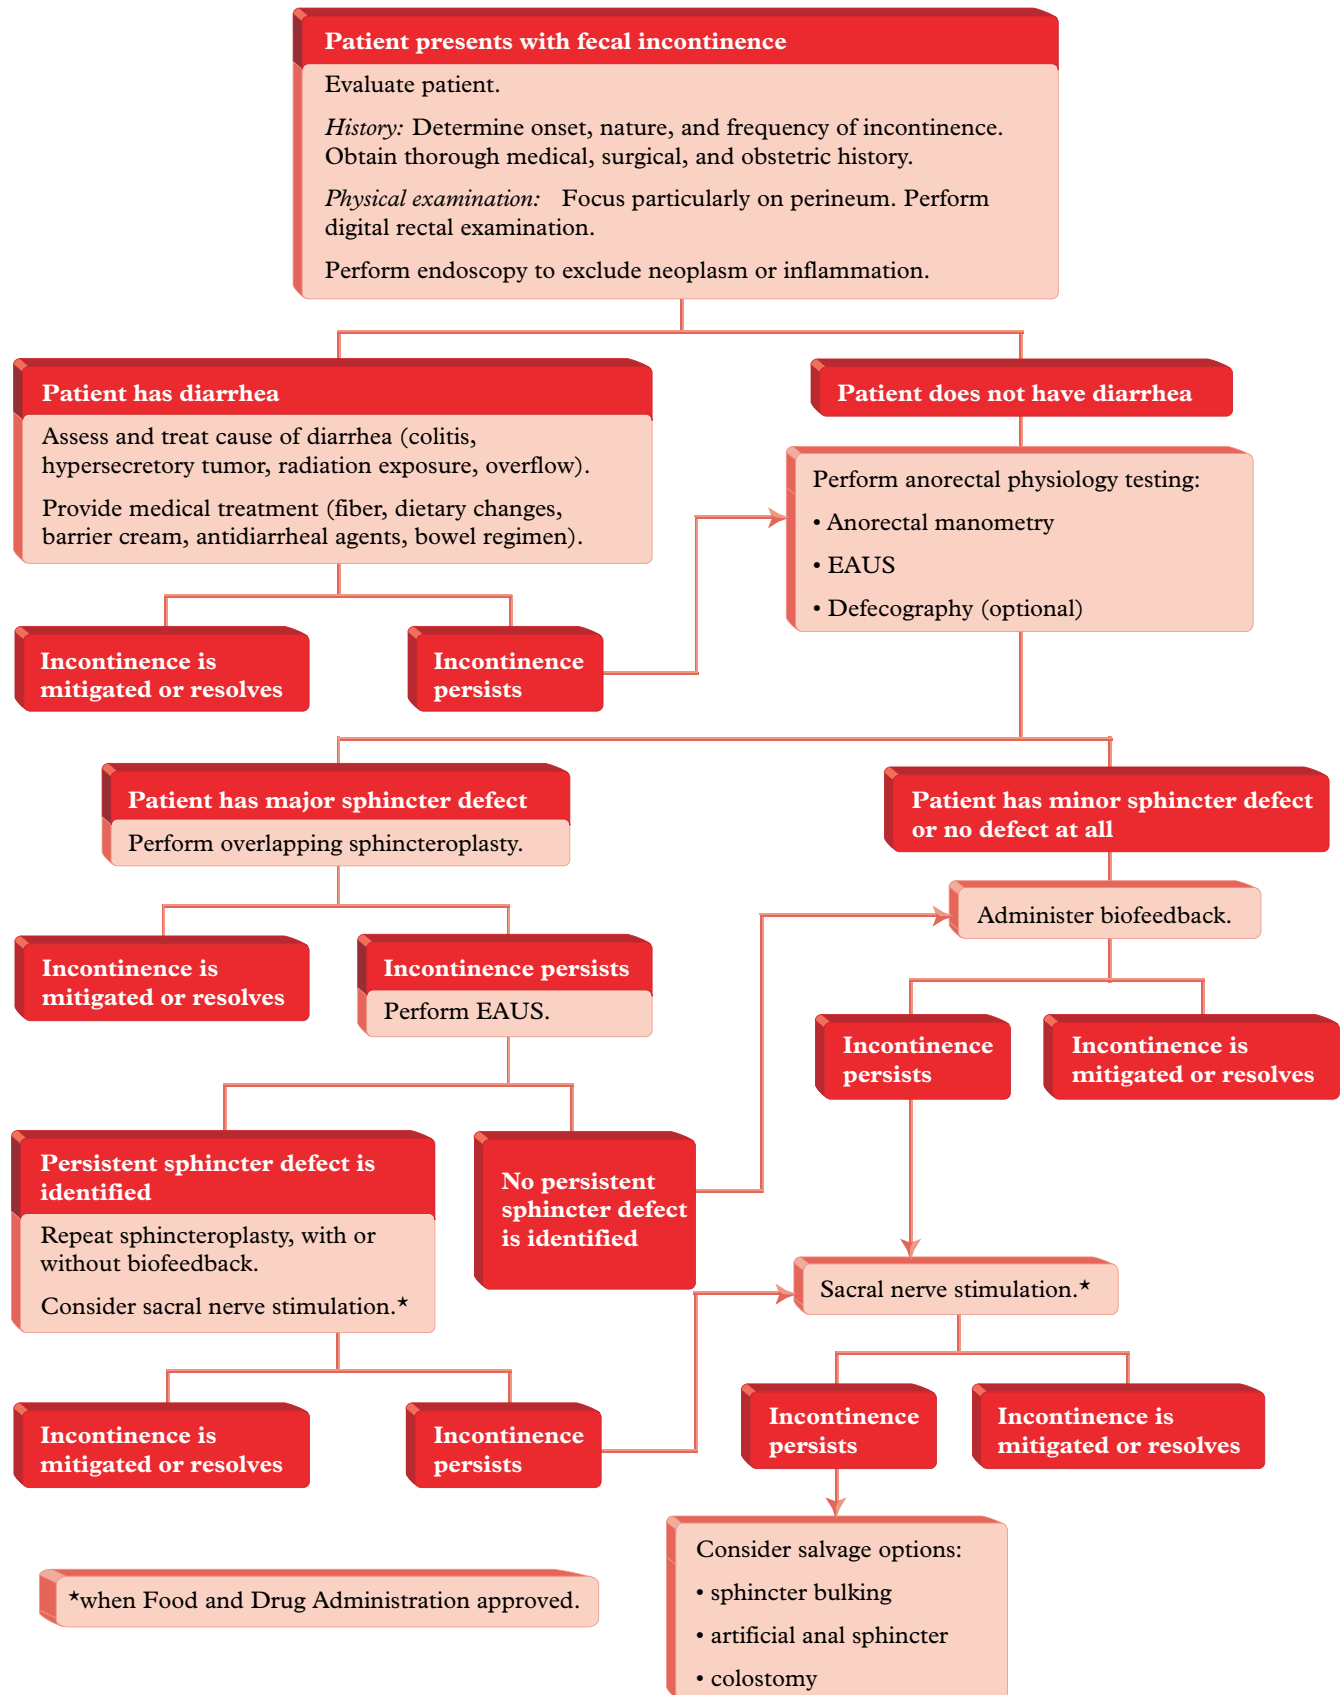

Figure 5 Algorithm outlining the workup and management of fecal incontinence. EAUS = endoanal ultrasonography.

Figure 6 Endoanal ultrasonograms show (a) a normal anal sphincter and (b) a sphincter defect.

curvilinear incision is made over the perineal body, and the anoderm and the anal canal mucosa are raised as an endodermal flap [see Figure 7a]. The vaginal wall is mobilized anteriorly.

Step 2: mobilization of sphincter muscle It is often easiest first to identify normal muscle laterally in the ischiorectal fossa and then to work medially toward the attenuated tissue in the midline. Lateral dissection is extended back on either side until enough healthy muscle is mobilized to allow overlapping without tension. Generally, however, lateral dissection should not extend beyond the midcoronal line so as not to risk injury to the inferior rectal branches of the pudendal

nerves, which cross the ischiorectal fossae posterolaterally. Dissection is then carried out cranially in the rectovaginal septum to the level of the puborectalis. The muscle is divided through its midline scar, but the scar is preserved to help prevent the sutures from tearing through.

Step 3: overlapping repair The tapes on the buttocks are then released, and an overlapping sphincter repair is performed with mattress sutures [see Figure 7, b and c]. A snug plication is universally advocated, but, unfortunately, there are no generally accepted objective criteria to define exactly what “snug” means in this context. Many authorities advise plication of the puborectalis (so-called levatorplasty) at the cranial aspect of the repair to maximize the length of the anal canal.⁸⁵ Others favor individual dissection and repair of the internal and external sphincter muscles, but at present, there is no compelling evidence for the superiority of this approach.

Step 4: restoration of perineal body The skin incision is closed in a V-Y configuration to restore the perineal body and maximize the distance between the anus and the vaginal introitus. The wound is left partially open or closed loosely over small Penrose drains to minimize the risk of surgical site infection [see Figure 7d]. A diverting stoma is not generally indicated but may be considered in special situations (e.g., multiple previous failed repairs, Crohn disease, or various chronic diarrheal states).

Outcome evaluation Overlapping sphincteroplasty yields substantial clinical improvement in approximately 65 to 80% of patients.^{86,87} Unfortunately, current data indicate that the results deteriorate significantly over time.^{88–90} When sphincteroplasty fails, repeat EAUS evaluation should be done to confirm that the muscle wrap is intact, and another repair should be performed after 6 to 12 months if a significant defect persists.⁹¹ If the muscle wrap is intact, the functional outcome can often be improved by means of biofeedback.⁹²

Various surgical options are available for patients in whom sphincteroplasty has failed or who are not candidates for the procedure (e.g., those with pudendal neuropathy and an anatomically intact sphincter). A number of these options are investigational, and further study is needed to determine their eventual role (if any) in incontinence therapy.

Postanal Repair

Sir Alan Parks devised the postanal repair in 1975 to treat patients with incontinence and intact sphincters. The initial results were encouraging but tended to deteriorate over time. Consequently, despite evidence of lasting improvement in some patients, this operation is rarely performed today.^{93,94}

Injectable Biomaterials

A number of studies have explored the use of injectable biomaterials to provide bulk around the anal sphincter and thereby improve continence. The materials employed have included autologous fat, cross-linked collagen, silicone, and carbon-coated beads.^{95,96} Several small, uncontrolled studies have reported promising results, but the sole randomized, controlled trial⁹⁷ identified in a recent systematic review⁹⁸ showed no difference between control and placebo arms. Additional randomized trials with longer follow-up times are needed.

Figure 7 Sphincteroplasty. (a) With the patient in the prone jackknife position, a curvilinear incision is made. Inferior rectal nerves cross the ischiorectal fossa posterolaterally. (b) Anterior levatorplasty is performed, and overlapping sphincter repair is then initiated. (c) Sphincter repair is completed. (d) The incision is closed, with drains in place (optional), and V-Y plasty is done to restore the perineal body.

Nonstimulated Muscle Transposition

Attempts to restore continence by creating a neosphincter from transposed skeletal muscle date back to the early 20th century. Most such attempts have made use of either the gluteus maximus⁹⁹ or the gracilis.¹⁰⁰ Good results have frequently been reported, but many authorities believe that the quality of the resulting continence is poor. One of the main limitations of nonstimulated muscle transposition is that patients are typically unable to maintain voluntary contraction of the transposed muscle over the long term.

Stimulated (Dynamic) Graciloplasty

Successful electrical stimulation of a transposed gracilis by means of an implantable pulse generator was first reported in 1988.¹⁰¹ Such stimulation has two main effects. First, it converts the fast-twitch, rapidly fatigable gracilis to a slow-twitch, fatigue-resistant muscle that is capable of tonic contraction for prolonged periods.¹⁰² Second, electrical stimulation maintains tonic muscle contraction without the need for continuous voluntary control on the part of the patient. A

small number of centers with particular expertise in dynamic graciloplasty and high patient volumes have reported good results with acceptable morbidities¹⁰³; however, three large multicenter trials have reported less encouraging results with prohibitive morbidities.^{104–106} In the United States, dynamic graciloplasty is not available, because it has not been approved by the FDA. Elsewhere in the world, the operation can be considered a salvage option at centers with the requisite expertise and experience.

Artificial Anal Sphincter

The artificial anal sphincter is an implantable system consisting of three parts: an inflatable perianal cuff, a pressure-regulating balloon, and a control pump that is implanted in the scrotum or the labia majora [see Figure 8]. Good results have been reported in individual case series,¹⁰⁷ but device infection has been a problem.^{108,109} In a large multicenter trial, 46% of patients required surgical revision of the device, including 25% who required revision or explantation because of infection.¹⁰⁸ Of the patients who underwent implantation,

Figure 8 Artificial anal sphincter. (a) A three-part implantable system is used (shown is Acticon, American Medical Systems, Minneapolis, MN). (b) Depicted is the recommended placement of the artificial sphincter device in the patient.

53% had successful results; among those with a functioning device in place, the success rate was 85%.

Sacral Nerve Stimulation

In SNS, an electrode is inserted through a sacral foramen and used to stimulate the sacral nerves. The procedure was originally used exclusively in patients with intact anal sphincters (including those with intact repairs), but more recent studies have shown efficacy in those with sphincter defects as well. SNS has recently been approved for the treatment of fecal incontinence in the United States by the FDA.

SNS is generally carried out in two stages. The first stage, peripheral nerve evaluation (PNE), is performed to confirm a muscular response to stimulation of the sacral nerves, to identify the optimal site for stimulation (S2, S3, or S4), and to determine the clinical response to stimulation with an external pulse generator. In most cases, stimulation of the S3 nerves provides the optimal response.

PNE is performed with the patient prone and under local anesthesia, with or without sedation. The sacral foramina are located by means of bony landmarks; S3 is typically about 1.5 cm off the midline at the level of the sciatic notch.¹¹⁰ Lead placement is optimally performed under fluoroscopic guidance. Initial testing is performed with an insulated spinal needle and an external pulse generator. Stimulation of each foramen leads to a typical response: S3 causes a bellows-type contraction of the pelvic floor and dorsiflexion of the ipsilateral great toe. Usually, several levels are tested until the optimal site is identified. A temporary pacing wire or a permanent quadripolar lead is then inserted and connected to an external stimulator [see Figure 9].

Patients are asked to provide a baseline continence diary, and a second diary is recorded during the test stimulation period. If continence is significantly improved (e.g., by 50% or more), the second stage of SNS, implantation of a permanent lead (if not already in place) and a pulse generator, is carried out. This second stage is also performed with the patient prone, under local anesthesia, and sedated. The pulse generator is implanted in a subcutaneous pocket on the same side as the stimulating electrode.

Both stages of SNS are performed as outpatient procedures. The pulse generator is activated and its stimulation parameters are set by means of a telemetric programmer. If problems (e.g., pain) develop or if the results of stimulation are inadequate, the system can be reprogrammed in a variety of ways: stimulation frequency can be altered, voltage can be increased or decreased, and the configuration of the stimulating electrodes can be modified.

SNS has been shown to be a highly effective treatment for fecal incontinence.^{111–113} Unlike dynamic graciloplasty and the artificial anal sphincter, SNS is associated with only minimal morbidity. In a multicenter prospective trial, the frequency of incontinent events dropped from 16.4/wk at baseline to 3.1/wk at 12 months after SNS and 2.0/wk at 24 months.¹¹⁴ Fecal incontinence–related quality of life was significantly improved. A more recent multicenter prospective trial showed that 83% of patients experienced a greater than 50% decrease in incontinent episodes per week compared with baseline at 12 months following SNS; 41% of patients attained full continence.¹¹⁵

Because of its high success rate and excellent safety profile, many authorities now consider SNS the salvage procedure of

Figure 9 Sacral nerve stimulation. (a) A lead containing four electrodes is used. (b) The sacral foramina are identified; in most cases, S3 is the optimal choice for stimulation. (c) Shown is the quadripolar lead in position.

choice for patients with refractory incontinence. If SNS fails, more aggressive treatments may still be tried at a later time.

Colostomy

Although creation of a colostomy does not restore continence, it does provide a degree of bowel control in a manner that allows patients to resume their normal activities without fear of accidents. Surprisingly few data are available regarding colostomy for incontinence; however, one questionnaire study of patients who underwent colostomy for incontinence

reported extremely high levels of patient satisfaction and marked improvements in subjective quality of life.¹¹⁶ In most cases, a simple end sigmoid colostomy with a Hartmann pouch is the appropriate procedure and can often be performed with relatively little operative trauma by using a laparoscopic or minilaparotomy technique. Patients should receive preoperative counseling from an enterostomal therapist, and the optimal stoma site should be marked before the procedure is initiated.

17 BENIGN AND MALIGNANT RECTAL, ANAL, AND PERINEAL PROBLEMS

David E. Beck, MD, FACS, FASCRS

Problems of the rectum, anus, and perineum are common, and an understanding of the anatomy is essential to properly diagnose and treat anorectal conditions.¹ As shown in Figure 1, the dentate line divides the rectal mucosa above (generally insensate and lined with columnar mucosa) and the anoderm below (highly sensitive because of somatic enervation provided by the inferior hemorrhoidal nerve and lined with modified squamous mucosa). The anal canal is surrounded by two muscles. The internal anal sphincter, innervated by the autonomic nervous system, maintains the resting anal tone and is under involuntary control. The external sphincter, innervated by somatic nerve fibers, generates the voluntary anal squeeze and is most important in maintaining anal continence. The area surrounding the anorectum is divided into four spaces, which are particularly important when evaluating perirectal abscesses and fistulas.

This chapter briefly reviews the evaluation and management of benign and malignant conditions of the anus and rectum, as well as retrorectal tumors. Rectal cancer is covered in another chapter of this text.

Benign Conditions

HEMORRHOIDS

Hemorrhoids are fibromuscular cushions that line the anal canal and are classically found in three locations: right anterior, right posterior, and left lateral.^{2,3} Smaller secondary cushions may occasionally lie between these main cushions. Contrary to popular belief, hemorrhoids are not related to the superior hemorrhoidal artery and vein, to the portal vein, or to portal hypertension.⁴ Hemorrhoids are part of normal

Figure 1 Depicted is the anatomy of the anal canal.⁵³

anatomy and become engorged during straining or performance of the Valsalva maneuver as a component of the normal mechanism of fecal continence. Hemorrhoidal engorgement most likely completes the occlusion of the anal canal and prevents the stool loss associated with nondefecatory straining. However, when the term “hemorrhoid” is used in the medical literature, it almost exclusively refers to pathologic hemorrhoids, and it will be used as such in the following paragraphs.

Hemorrhoids are divided into internal and external components. Internal hemorrhoids are found proximal to the dentate line, whereas external hemorrhoids occur distally [see Figure 2]. External hemorrhoids are redundant folds of perianal skin generally related to previous anal swelling; they remain asymptomatic unless they are thrombosed and are treated entirely differently from internal hemorrhoids.

Internal Hemorrhoids

Evaluation Internal hemorrhoidal disease is demonstrated by two main symptoms: painless bleeding and protrusion.⁴ Pain is rarely associated with internal hemorrhoids because they originate above the dentate line in insensate rectal mucosa. The most popular etiologic theory states that hemorrhoids result from chronic straining at defecation (upright posture and heavy lifting may also contribute). This straining not only causes hemorrhoidal engorgement but also creates forces that decrease the fixation between the hemorrhoids and the anal muscular wall. Continued straining causes further engorgement and bleeding, as well as hemorrhoidal prolapse. Internal hemorrhoids are categorized into four grades based on clinical findings and symptoms: 1, bleeding without prolapse;

2, prolapse that spontaneously reduces; 3, prolapse requiring manual reduction; and 4, irreducible prolapse.

Questioning often reveals a long history of constipation and straining at defecation. Patients with internal hemorrhoids are commonly extensive bathroom readers, spending many hours in the bathroom each week. Symptoms start with painless bleeding and may progress to anal protrusion. Hemorrhoidal prolapse must be distinguished from true full-thickness rectal prolapse. The physical examination begins with visual inspection and may reveal prolapsing hemorrhoidal tissue as a rosette of three distinct pink-purple hemorrhoidal groups. If prolapse is not present, anoscopy reveals redundant anorectal mucosa just proximal to the dentate line in the classic locations.

Surgical treatment of hemorrhoids in a patient whose main disease process is Crohn disease, a pelvic floor abnormality, or fissure disease invariably yields imperfect results. It is especially important to recognize anal pain and spasm and fissure in ano because in patients with this problem, excision of the hemorrhoids without concomitant management of the fissure leads to increased postoperative pain and poor wound healing. Not uncommonly, patients are treated for hemorrhoids when the true primary condition is fissure disease.

Treatment Treatment for symptomatic internal hemorrhoids varies from simple reassurance to operative hemorrhoidectomy [see Table 1]. Treatments are classified into three categories: (1) dietary and lifestyle modification; (2) nonoperative or office procedures; and (3) operative hemorrhoidectomy. All patients with grade 1 or 2 hemorrhoids and most patients with grade 3 hemorrhoids should be

Figure 2 Separate external and internal hemorrhoids are seen on the left and a combined internal-external hemorrhoidal complex is seen on the right.

Table 1 Treatment Alternatives for Hemorrhoids

Treatment	Internal (Grade)				External
	1	2	3	4	
Diet modification	X				
Sclerotherapy	X	X			
Infrared coagulation	X	X	(X)		
Rubber band ligation	(X)	X	X		
Stapled anoplasty (PPH)		X	X		
Excisional hemorrhoidectomy		(X)	X	X	X

PPH = procedure for prolapsing hemorrhoids; (X) = selected patients.

treated initially with efforts to correct their constipation. Recommendations should include a high-fiber diet; liberal water intake (six to eight 8-ounce glasses of water daily); fiber supplements such as psyllium, methylcellulose, calcium polycarbophyl, or gum; or stool modifiers such as polyethylene glycol. Sitz baths are recommended for their soothing effect and ability to relax the anal sphincter muscles. Topical creams may reduce some associated symptoms but do not affect the hemorrhoids themselves. Suppositories are avoided as they deliver medication to the rectum and not the anus. Patients are instructed to avoid prolonged trips to the bathroom, and reading should be performed only when sitting atop the toilet lid. If these initial measures are not effective,

a number of nonoperative therapies are available. Current recommended options include rubber band ligation, infrared photocoagulation, and sclerotherapy.

Rubber band ligation is currently the most common method in use for the outpatient treatment for hemorrhoids.⁵ One to three bands are applied. Complications of hemorrhoid banding include bleeding, pain, thrombosis, and life-threatening perineal sepsis.^{5,6} The cardinal signs of perineal sepsis are significant pain, fever, and difficulty urinating. Patients developing any of these symptoms require urgent evaluation and treatment with broad-spectrum antibiotics and selective débridement of any anal necrotic tissue.

Hemorrhoidal banding is successful in two thirds to three quarters of all individuals with first- and second-degree hemorrhoids.² Repeated banding may be necessary to resolve all symptoms. Rarely, individuals fail to respond whatsoever or cannot tolerate banding. Some of these patients will respond to infrared coagulation, whereas others may require formal hemorrhoidectomy.

The infrared photocoagulator generates infrared radiation, which coagulates tissue protein and evaporates water from cells.⁷ The amount of destruction depends on the intensity and the duration of application. An anoscopic examination is performed, and the infrared coagulator is applied to the apex of each hemorrhoid at the top of the anal canal [see Figure 3]. A duration of 1 to 1.5 seconds is used to treat each hemorrhoid bundle three to four times. The infrared coagulator was designed to decrease blood flow to the region and is less

Figure 3 The infrared coagulator is applied to each hemorrhoid bundle three or four times for 1 to 1.5 seconds at a time.⁴

Figure 4 The infrared photocoagulator creates a small thermal injury. Thus, several applications are required for each hemorrhoidal column.⁴

effective in treating large amounts of prolapsing tissue. It is most beneficial in grade 1 and small grade 2 hemorrhoids. It is slightly less painful than rubber banding. This technique is especially useful in patients who fail banding secondary to pain or have symptomatic internal hemorrhoids that are too small to band.

Sclerotherapy was common in the past but with the advent of rubber band ligation is currently less popular. The technique involves injection of an irritating material into the anorectal submucosa to decrease vascularity and increase fibrosis. Injecting agents include phenol in oil, sodium morrhuate, or quinine urea.² The hemorrhoids are identified with an anoscope, and the injecting agent is infiltrated at the apex of the hemorrhoid (proximal anal rectal ring). This occasionally produces a dull ache lasting 24 to 48 hours but rarely results in significant bleeding or other complications. There have been rare reports of misplacement of the sclerosing agent resulting in significant perianal infection and fibrosis.

A meta-analysis comparing a variety of modalities used to treat hemorrhoids found that rubber band ligation was better than sclerotherapy for grade 1 to 3 hemorrhoids.⁸ Patients who were treated with sclerotherapy or infrared coagulation were more likely to require further treatment than those treated with rubber band ligation. Hemorrhoidectomy should be reserved for patients in whom rubber band ligation or infrared coagulation fails or who have associated external hemorrhoidal disease.

Various types of hemorrhoidectomies have been developed throughout the years, but they are all associated with similar basic principles. These include decreasing blood flow to the anorectal ring, removing redundant hemorrhoidal tissue, and fixation of redundant mucosa and anoderm.⁹ Details of the various procedures (Milligan and Morgan [open], Ferguson [closed], or procedure for prolapsing hemorrhoids) are described elsewhere [see 5:37 *Anal Procedures for Benign Disease*].^{10,11}

External Hemorrhoids

External hemorrhoids are asymptomatic except when secondary thrombosis occurs. Thrombosis may be the result of

defecatory straining or extreme physical activity, or it may be a random event.¹ Patients present with acute onset of constant anal pain and often report a sensation of sitting on a tender marble. The physical examination identifies the external thrombosis as a purple mass at the anal verge. The treatment is dependent on the patient's symptoms [see Figure 4].⁴ In the first 24 to 72 hours following the onset of thrombosis, the pain increases, and excision is warranted. After 72 hours, the pain generally diminishes, and expectant treatment is all that is necessary. Patients should be advised that some drainage may occur. If operative treatment is chosen, the entire thrombosed hemorrhoid is excised under local anesthesia. Incision and drainage of the clot is avoided as this often results in rethrombosis and worsening symptoms.

ANAL FISSURE

An anal fissure is a tear or split in the anoderm just distal to the dentate line.¹² Fissures are characterized as acute or chronic. An acute fissure is generally caused by the mechanical force of a large, hard bowel movement being passed through an anal canal too small to accommodate safe, easy passage (although diarrhea can also cause anal fissures). These forces usually cause a split to occur in the posterior midline (90% of the fissures in females and 99% of fissures in males are located posteriorly). Decreased local blood flow or increased mechanical stress may account for these fissures' propensity to occur posteriorly.¹³ Repeated injury (e.g., from hard or watery bowel movements) can result in development of a chronic fissure.

Symptoms associated with anal fissures include anal pain and bright red rectal bleeding associated with bowel movements. The pain is usually described as a knifelike pain or tearing sensation, and the associated anal sphincter spasm may persist for several hours following each bowel movement. The bleeding is usually minor, red in color, and seen mainly on the toilet paper. Physical examination is difficult because the patient has an extremely tender anus and is fearful. Often visual inspection with gentle eversion of the anoderm in the posterior midline is all that is required. Physical findings include an approximately 1 cm split in the anoderm in the posterior midline just distal to the dentate line. In

Figure 5 Chronic anal fissures, as opposed to acute fissures, are characterized by hypertrophy of the anal papilla, a sentinel skin tag, rolled skin edges, and exposed internal anal sphincter muscle.

chronic fissures, the classic triad may be present: hypertrophy of the anal papilla, anal fissure, and sentinel skin tag [see Figure 5]. Once an anal fissure has been diagnosed, further examination is very painful, unrewarding, and unnecessary. More extensive investigations can be performed after the fissure has healed.

Multiple fissures, or fissures occurring away from the anterior or posterior midline, are unusual and should raise suspicion for other problems as described in Figure 6.

Acute fissures are usually present for less than 4 to 6 weeks and are usually treated nonoperatively. Fiber supplements, stool softeners, and generous intake of water, along with sitz baths and local anesthetic ointments, improve symptoms rapidly and usually result in complete healing. Anal suppositories are avoided as they are painful and rest in the rectum rather than the anal canal.

Chronic fissures have been present for longer periods (greater than 4 to 6 weeks) and usually have an associated hypertrophied papilla and skin tag, rolled skin edges, and exposed internal anal sphincter muscle at the base of the fissure. Chronic fissures respond less successfully to nonoperative measures. The most common surgical procedure is a lateral internal anal sphincterotomy.¹⁴ In this procedure, the internal sphincter distal to the dentate line is cut in a lateral aspect of the anal canal. This allows for relaxation of the forces keeping the fissure from healing and results in cure in 95 to 98% of patients. Complications of sphincterotomy include incontinence to flatus (0 to 18%), soiling (0 to 7%), fecal incontinence (0 to 0.17%), and miscellaneous (0 to 7%).¹⁴

To avoid an operation and the possibility of complications, several alternatives have been proposed.¹⁵ On the theory that a fissure is actually an ischemic ulcer of the anoderm, topical

nitroglycerin (0.2% NTG) ointment has been used with success rates varying from 48 to 78%. The actual dosing is limited by its side effects, which may occur in up to 88% of patients. Headaches are the predominant complaint, but dizziness, lightheadedness, and hypotension may also occur. Caution must be exercised with this therapy in patients on cardiac medications and those with sensitivities to nitrates. A meta-analysis comparing topical NTG with sphincterotomy demonstrated that sphincterotomy is superior to topical NTG in the healing of chronic fissures.¹⁶

Nifedipine, a calcium antagonist, has been applied topically in a 2% nifedipine ointment, with results similar to those of NTG but with fewer side effects. Caution is recommended for cardiac patients. One multicenter study reported a 95% complete healing rate after 21 days of treatment.¹²

Botulinum toxin has been reported to facilitate the healing of fissures in 78 to 90%, with an 8% recurrence rate in 6 months.^{15,17} The toxin, produced by the bacterium *Clostridium botulinum*, acts by inhibiting the release of acetylcholine at the presynaptic membrane. As a result of blocked neurotransmission, spasms and contractions of the sphincter mechanism are diminished or eliminated. Injections of 2.5 to 50 units are administered in two to four sites in the internal sphincter at the level of the dentate line.¹⁸ Although it still takes days for the fissure to heal, pain relief is generally noted within 24 hours. Postinjection incontinence is rare, but an 8% recurrence rate has been reported.¹² The major drawback is the cost of the toxin, which may be \$400 per 100-unit vial.

None of these alternatives has received a Food and Drug Administration indication for the treatment of anal fissures. An algorithm for the management of anal fissures is presented in Figure 7.

Figure 6 The location of anal fissures suggests their cause.⁴

Figure 7 Algorithm for the management of anal fissures.

ANORECTAL ABSCESS

Anorectal abscesses are the result of local, walled-off infections of a cryptogenic origin.^{18,19} That is, they begin as infections in the anal glands that surround the anal canal and empty into the anal crypts at the dentate line. The ducts leading to and from these glands are thought to become obstructed as a result of feces or trauma, and a secondary infection develops that follows the path of least resistance, resulting in an anorectal abscess.

Abscesses are characterized as perianal, ischiorectal, supralevator, or intersphincteric [see Figure 8]. Perianal abscesses are the most common; together with ischiorectal abscesses, they account for more than 90% of perianal infections. Perianal abscesses occur in the perianal space immediately adjacent to the anal verge. Ischiorectal abscesses are larger and often more complex than their perianal counterparts, and they usually present as a tender buttock mass. Supralevator abscesses occur above the levator ani muscles, present with poorly localized pain, and are exceedingly rare. Intersphincteric or intermuscular abscesses occur in the plane between the internal and external sphincters, high within the anal canal. The location of an abscess is important as it dictates subsequent therapy.²⁰

Regardless of their location, anorectal abscesses are associated with constant perianal pain. Accompanying symptoms may include fever, chills, and malaise. In rare cases, systemic toxicity may be evident. History reveals a gradual onset of rectal pain that progressively increased until the time of presentation. Occasionally, spontaneous drainage decompresses the abscess, and the patient presents with a purulent discharge.

Again, visual inspection of the perineum often clinches the diagnosis. A fluctuant, erythematous, tender area identifies the abscess. In the rare case of a supralevator or intersphincteric abscess, there may be no external manifestations, and a tender mass on digital examination above the anal canal, adjacent to the rectal ampulla (supralevator abscess), or within the anal canal (intersphincteric abscess) provides the clue to diagnosis.

Figure 8 Anorectal abscesses are classified according to the space in which they develop.

The treatment for anorectal abscesses is adequate drainage performed either in the office, the emergency room, or the operating room.¹⁸ Most abscesses can be drained in the office, but recurrent or complex abscesses, abscesses in immunosuppressed hosts (including some diabetics), and intersphincteric or supralevator abscesses are more appropriately drained in the operating room.

Adequate drainage is essential and may be established in several ways. One method is to place a catheter (such as a 10 to 16 French de Pezzer catheter) through a small stab incision.¹⁸ This allows the pus to drain through the catheter as the cavity closes down. After the cavity closes down, the catheter is removed, and the small remaining cavity heals. The incision for the catheter is placed over the fluctuant area, as close to the anal canal as possible. This results in a shorter fistula tract if the abscess does not heal completely. A second drainage option involves creating a larger elliptical incision.²⁰ Unroofing the abscess cavity allows it to heal without the need for packing. A small incision should be avoided as it requires painful packing to keep the skin open until the abscess cavity heals.

The most difficult and potentially quite serious abscess to diagnose and manage is a deep postanal space abscess. Deep postanal space abscesses are caused by fistulization from the posterior anal canal, usually in the bed of a chronic posterior fissure. The patient is impressively uncomfortable and febrile, but there is no apparent sign of a problem perianally. A simple digital examination pushing posteriorly toward the coccyx and deep postanal space is extremely uncomfortable and leads one to suspect the diagnosis. The patient should be taken to the operating room and anesthetized. The deep postanal space is often felt on digital examination to be bulging. The diagnosis is confirmed by aspirating this space with an 18-gauge needle. Once the diagnosis is confirmed, then an incision is made in the perianal skin posterior to the anal verge and deepened into the space. The space is adequately drained. In selected patients, a cutting seton is placed from the primary site in the posterior anal canal directly into the deep postanal space abscess. Any horseshoeing is dealt with using counterincisions.

Following adequate drainage, antibiotics are rarely needed. Patients should be discharged with fiber supplements (stool softeners), pain medication, and instructions for sitz baths two to three times daily.

FISTULA IN ANO

An anal fistula is a communication from the anal canal to the perianal skin. The fistula usually begins in a crypt at the dentate line and follows a course between the internal and external sphincters (the most common location), resulting in an ischiorectal abscess, or above the sphincters, leading to a supralevator abscess.^{18,20} Following acute drainage of an abscess, one of three things may occur if a fistula is present: (1) the fistula will heal spontaneously, and the patient will experience no further symptoms; (2) the abscess may heal only to recur in the future; or (3) the abscess may heal, leaving a chronic draining anal fistula or fistula in ano. Only the third scenario is discussed here.

Following drainage of one or more abscesses, a fistula is usually associated with chronic serosanguineous to

Figure 9 Goodsall's rule. An external opening seen posterior to a line drawn transversely across the perineum will originate from an internal opening in the posterior midline. An anterior opening will originate in the nearest crypt (for fistulas within 23 cm of the anus).⁴

seropurulent drainage. As long as the fistula remains open and draining, patients report little pain. But should the fistula close externally, an anorectal abscess may develop. Physical examination reveals a 2 to 3 mm opening in the perianal skin, with surrounding induration. Often a fistula tract may be palpated as a firm cord running between the external opening and the anal canal. The relationship of the external opening to the internal opening is suggested by Goodsall's rule [see Figure 9]. Fistulas are classified according to their relation to the anal sphincters [see Figure 10].²¹

Essentially, all chronic fistulas require surgical treatment. The most common option consists of unroofing the entire fistula tract (fistulotomy) and leaving the wound open to heal secondarily. Fistulas that course through significant amounts of sphincter muscle, are anterior in women, or are associated with inflammatory bowel disease or weakened sphincter muscles cannot be opened entirely because incontinence will result. These fistulas may be partially opened, leaving the anal musculature intact, which is encircled with a seton.²⁰ A seton is a nonabsorbable suture (e.g., 0 silk) or elastic suture (Silastic vessel loop) that is inserted into the fistulous tract, and the ends of the suture or elastic are tied with multiple knots to

Figure 10 Fistula in ano is classified on the basis of its relation to the anal sphincter muscles. Shown are (a) intersphincteric fistula, (b) transsphincteric fistula, (c) suprasphincteric fistula, and (d) extrasphincteric fistula.

create a handle for manipulation. The seton may serve to facilitate drainage or stimulate fibrosis adjacent to the sphincter muscle to prevent gaping of the sphincter at a secondary stage repair. The seton allows delineation of the amount of remaining muscle. Although some surgeons sequentially tighten the seton (cutting seton), the author avoids this technique because of the resultant patient discomfort. A third option involves closing the internal fistula opening with an advancement flap.²² Advancement flap repairs result in high success rates, with minimal effects on continence. Additional, newer options include an anal fistula plug or a lateral internal anal fistula transaction (LIFT) procedure.²³

PILONIDAL DISEASE

The term *pilonidal disease* is derived from the Latin “pilus” (hair) and “nidus” (nest).²⁴ The term denotes a chronic subcutaneous infection and foreign body reaction to hairs embedded in the skin or abnormalities of hair follicles in the natal cleft.²⁴

Pilonidal disease is more common in men, between puberty and 40 years of age, and obese patients.²⁴ Pilonidal disease has three common presentations. Nearly all patients have an episode of acute abscess formation. When this abscess resolves, either spontaneously or with medical assistance, many patients will develop a pilonidal sinus. Although most sinus tracts resolve, a small minority of patients will develop chronic disease or recurrent disease after treatment.

Physical examination typically reveals one or more small (1 to 2 mm) dermal pits at the base of the intergluteal cleft [see Figure 11]. Tracking from the pits (usually in a cranial and lateral direction) will appear as areas of induration. With an associated abscess, the diseased area may be tender and erythematous, and draining pus may be evident. The more

extensive the disease is, the more prominent the findings are. Treatment methods vary for each stage in pilonidal disease.

Abscesses must be drained. Incision and drainage in an office setting using local anesthesia resulted in healing in 60% of patients.²⁵ Up to 40% of acute pilonidal abscesses treated by incision and drainage form a chronic sinus that requires additional treatment. A review of articles published in the last 30 years on the treatment of pilonidal disease divided the procedures and analyzed them by broad category.²⁶ Closed techniques (coring out follicles and brushing the tracts) required shaving of the area but could be performed on an outpatient basis. The mean healing time was about 40 days, and recurrence rates were slightly higher than with other forms of treatment. Laying open (unroofing) the tracts with healing by granulation resulted in average healing times of 48 days and required frequent outpatient dressing changes. The incidence of recurrent sinus formation was less than 13%. Wide and deep excision of the sinus alone resulted in an average healing time of 72 days and recurrent rates similar to those for simple laying open of the sinus with wound granulation. Excision and primary closure resulted in wound healing within 2 weeks in successful cases (19 days overall). However, up to 30% of patients failed primary wound healing, and the average recurrence rate for these experienced authors was 15%. A nonoperative or conservative approach has been suggested as an alternative to conventional excision.²⁷ In this approach, meticulous hair control by natal cleft shaving, improved perineal hygiene, and limited lateral incision and drainage for treatment of abscess have resulted in a significant reduction in the number of excisional procedures and occupied-bed days.

Even with proper treatment, a small subgroup of patients are left with persistent, nonhealing wounds. A number of more aggressive treatments have been described to treat complex or recurrent disease, including wide excision and split-thickness skin grafting, cleft closure, and excision and closure with various types of flaps.^{25,28} These flap techniques as a group have resulted in primary healing in less than 15 days in 90% of cases.²⁵ There are, however, disadvantages to these aggressive approaches. Nearly all of these techniques require hospitalization and general anesthesia. In addition, up to 50% of those procedures requiring skin flaps for wound coverage or closure develop loss of skin sensation or flap tip necrosis.

The author recommends drainage of acute abscesses followed by measures to keep the cleft free of hair. Chronic disease is managed by unroofing or excision and closure in selected patients. Flap procedures are reserved for extensive, recurrent, and complex disease.²⁴

HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa is a chronic, recurrent inflammatory process involving the apocrine glands of the axilla, groin, perineal, and perianal regions.²⁹ The disease can become quite painful and debilitating, resulting in chronically draining wounds and sinus tracts.³⁰ Occlusion of follicles and abnormalities of apocrine ducts are considered etiologic factors.

Medical management may afford temporary relief of symptoms; however, most patients will eventually require surgical therapy.³¹ Incision and drainage or unroofing of sinuses may provide relief in selected patients but should be reserved for

Figure 11 Patients with pilonidal disease generally have one or two dermal pits in the intergluteal cleft, often associated with a sinus and an abscess.

early and acute disease. Local excision will provide adequate control of symptoms; however, greater than 50% recurrence can be anticipated. Wide excision with secondary granulation of perineal wounds will provide the most definitive therapy and can be accomplished safely.³⁰ Perianal disease can more often be managed with local excision alone as recurrence rates of perianal disease are considerably lower than for perineal disease.

PRURITUS ANI

Pruritus ani is a dermatologic condition of the perianal skin characterized by a symptom complex of uneasiness or itching in the perianal area.^{31,32} Factors predisposing the anal area to irritation are poor perianal hygiene (incontinence, diarrhea, excessive hair), excessive moisture, irregularities of the perianal skin (hemorrhoids, fistula, previous surgery), skin hypersensitivity, diet, decreased resistance to infection, and injury to the perianal skin.³² These multiple possible etiologic factors are what can make pruritus ani refractory to treatment. Some patients improve only after the offending agent or agents are identified and specific therapy is instituted. Fortunately, many patients' symptoms improve by the application of non-specific treatments.

A thorough history and physical examination are necessary to suggest possible causes of pruritus. Initial inspection of the perianal skin should be conducted with bright lighting and gentle retraction of the buttocks. Characteristic findings include erythematous or thickened perianal skin [see *Figure 12*].

Figure 12 A characteristic finding in idiopathic pruritus ani is erythematous or thickened perianal skin.⁴

The thickening results in a pale, whitish appearance with accentuation of the radial anal skin creases. In addition, the skin may be excoriated or ulcerated, which, when combined with thickening, is referred to as lichenification. Occasionally, the skin may be so excoriated as to present as a large, coalescing, weeping ulcer. Digital rectal examination should be performed to assess anal sphincter competence both at rest and during maximal squeeze. Anoscopy and proctosigmoidoscopy can be performed following the administration of an enema.

The principles of treating pruritus ani are simple. If an inciting cause can be identified, it should be eliminated or corrected. Frequently, the cause of pruritus is elusive, but most patients can be managed using several simple principles. Patients should keep the perianal area dry and avoid further trauma to the perianal area. The perianal area should be gently washed, never scrubbed. After showering, the area should be patted dry or dried using a hair dryer on a low heat setting. Following bowel movements, the anus should be cleaned using moistened toilet paper. Excessive rubbing or wiping should be discouraged. Scratching or rubbing the anal area damages the perianal skin, making it more susceptible to irritation.

Patients should be instructed to avoid irritating foods and drinks such as tomatoes, peppers, citrus fruits and juices, coffee, colas, beer, alcoholic beverages, milk, nuts, popcorn, or any other foodstuffs found to be associated with increased gas, indigestion, or diarrhea. After 2 weeks, eliminated food items can be reintroduced one at a time in an attempt to identify the offending agent more specifically.

A regular bowel habit should be maintained using fiber supplementation or a high-fiber diet. Patients should be instructed to eschew all proprietary creams, lotions, or emollients. If prescribed and supervised by a physician, a hydrocortisone cream may be applied sparingly to the affected area for a period of a week or less to initiate control of symptoms. Occasionally in refractory cases, a candidal yeast infection exists, and a trial of antifungal lotion, solution, or powder is worthwhile. In general, the principles of treating pruritus ani are to establish and maintain an intact, healthy, clean, and dry perianal skin. In cases that fail to improve, fungal and viral cultures and even biopsy may be necessary to exclude an infectious or neoplastic cause.

SOLITARY RECTAL ULCER SYNDROME

Solitary rectal ulcer syndrome (SRUS) is a clinical condition characterized by rectal bleeding, copious mucous discharge, anorectal pain, and difficult evacuation.³² Despite its name, with this condition, patients can have single, multiple, or no rectal ulcers.³³ When present, the ulcers usually occur on the anterior rectal wall just above the anorectal ring. Less commonly, they may occur from just above to 15 cm above the dentate line. Ulcers usually appear as shallow with a "punched out" gray-white base surrounded by hyperemia.³⁴

Cystica profunda (CCF) is a related benign condition characterized by mucin-filled cysts located deep to the muscularis mucosae. CCF is a pathologic diagnosis whose most important aspect is to differentiate it from colorectal adenocarcinoma. The etiology of these conditions remains unclear, but a common feature is chronic inflammation and/or trauma (internal intussusception or prolapse of the rectum, direct digital trauma, or the forces associated with evacuating a hard stool).

An endoscopic evaluation of the distal colon and rectum will reveal the lesions described above. The differential diagnosis of both CCF and SRUS includes polyps, endometriosis, inflammatory granulomas, infectious disorders, drug-induced colitides, or mucus-producing adenocarcinoma. Differentiation among these entities is possible with an adequate biopsy.

Treatment is directed at reducing symptoms or preventing some of the proposed etiologic mechanisms. Conservative therapy (high-fiber diet, lifestyle changes, and biofeedback) will reduce symptoms in most patients and should be tried first. Patients without rectal intussusception are offered biofeedback to retrain their bowel function. Pharmacologic therapy (antiinflammatory enemas or suppositories) has had limited success but is reasonable to try before embarking on surgery. If symptoms persist, a localized resection may be considered in selected patients. Patients with prolapse are considered for perineal procedures (mucosal or perineal proctectomy) and abdominal procedures (fixation or resection and rectopexy). Patients without prolapse may be offered excision, which varies from a transanal excision to a major resection with coloanal pull-through. Surgeons have been understandably hesitant to offer surgical therapy for this benign condition, and the results are often unsatisfactory.^{35,36}

Malignant Conditions

Anal neoplasms are uncommon, with an incidence one twentieth that of rectal adenocarcinoma or 1.5 to 4% of large bowel cancers.²⁸ Current statistics indicate that this incidence is increasing, and the management of these tumors has recently undergone significant changes.

ANATOMY

For clinical purposes, the anus can be divided into two areas: the anal canal and the anal margin [see Figure 1]. The anal canal runs from the anorectal junction (top of the anal sphincter muscles) to the intersphincteric groove (approximately 2 cm distal to the dentate line). Thus, it corresponds to the internal sphincter. The lining of this portion of the anus is formed by transitional epithelium, which contains elements of both columnar and squamous epithelium above the dentate line and squamous epithelium distal to the dentate line.

The anal margin runs from the intersphincteric groove to approximately 5 cm on the perineum. This area is covered by nonkeratinizing squamous epithelium, which changes to keratinizing squamous epithelium at the anal margin's outer border with the perineal skin.

ANAL CANAL

Epidermoid Carcinoma

Epidermoid carcinomas are the most common forms of anal canal neoplasms.³⁷ On histologic review of these neoplasms, 70% are found to be squamous cell neoplasms, 25% are basaloid neoplasms, and 5% are mucoepidermoid. Clinically, the different histologic types act in a similar manner.

The lymphatic drainage of the anus follows the arterial vessels. Thus, metastatic anal disease can spread in three different directions. Superiorly, this includes the pararectal and superior hemorrhoidal nodes; laterally, the internal iliac

nodes; and inferiorly, the inguinal and external iliac nodes. For prognostic purposes, anal canal cancers have been grouped into four stages: stage 1 tumors are confined to the sphincteric mechanism, stage 2 have extended into the perirectal fat, stage 3 have involved lymph nodes, and stage 4 have distant metastases. Other staging systems have been described, and the TNM system has been adopted by the American Joint Committee on Cancer [see Table 2]. Unfortunately, lymph node involvement is difficult to determine in the absence of surgical specimens.

Diagnosis Patients with anal cancer usually present with bleeding per rectum and pain. The bleeding is red and usually more constant than that associated with hemorrhoids.³⁸ The pain is less severe than with an acute fissure and more constant. An occasional patient will also complain of an ulcerated or mass lesion of the anus. Additional questions help evaluate these symptoms and exclude other differential diagnoses.

The physical examination is helpful in making the diagnosis and is essential to determine the clinical stage of disease. Anal cancers are within reach of the examining finger and are hard, irregular, and usually ulcerated [see Figure 13]. The exact location and size of the lesion must be documented. This includes the vertical and horizontal diameters of the lesion and the height above the anal verge. The anatomic location (e.g., anterior versus posterior and right or left) should also be noted. An assessment of the lesion's fixity, relation to other structures, and status of the sphincteric muscles completes the perineal examination. In addition to an evaluation of the lesion, the patient should be examined for the presence of inguinal adenopathy.

Direct visualization of the anus and rectum is essential to exclude other lesions and allows biopsy of the lesion to confirm the clinical diagnosis. Anoscopy provides good exposure and is the least expensive method to examine the anal canal. After identification, the lesion should undergo biopsy. Several specimens should be obtained from the edges of the lesion. A local anesthetic is usually not required.

Table 2 Tumor Node Metastasis (TNM) Staging System for Anal Cancer

Stage	Description
T1	Carcinoma < 2 cm in diameter
T2	> 2 and < 5 cm in diameter
T3	> 5 cm in diameter
T4	Invading adjacent organ
N0	No regional node involvement
N1	Metastasis in perirectal lymph nodes
N2	Metastasis in unilateral iliac or inguinal nodes
N3	Metastasis in bilateral iliac or inguinal nodes
M0	No distant metastasis
M1	Distant metastasis

Figure 13 Anal cancer.

To assist in clinical staging, several modalities are currently available. Anorectal ultrasonography is being used with increased frequency and is helpful in assessing the depth of anal tumors and in identifying the presence and characteristics of lymph nodes. The difficulty remains with the identification of suspicious nodes. The quality of the examination depends on the operator, and further widespread experience is necessary.

Computed tomographic (CT) scans help assess the extent of the primary tumor and the presence of enlarged lymph nodes. A scan can determine the size and location of lymph nodes but, again, cannot accurately determine if the nodes contain tumor. This study can also evaluate the liver to exclude the presence of large hepatic metastases (greater than 1 cm). Magnetic resonance imaging (MRI) is also being used to stage anal cancer.

Treatment Anal cancer is currently treated by surgery and chemoradiotherapy. Surgical options include transanal excision and abdominoperineal resection (APR). For early lesions, local excision (transanal excision) is a valid consideration but must be limited to lesions that are well differentiated, less than 2 cm in diameter, and located in the distal anal canal. The procedure is similar to that described for early rectal cancers. Using this procedure in selected patients, the reported 5-year survival has ranged from 45 to 100%.^{39,40} An APR performed for anal cancer is similar to that described for rectal cancer, with the exception that a slightly wider margin of perineal skin is removed. This

procedure is used in patients who cannot undergo chemoradiotherapy or fail this therapy. The 5-year survival rate after this form of treatment averaged 50%, with a published range of 30 to 70%, and local recurrence ranged from 11 to 40%.^{39,41}

Inadequate results from surgery or radiotherapy alone led Nigro at Wayne State University to propose initial chemotherapy (5-fluorouracil [5-FU], mitomycin C) and radiotherapy followed by APR.³⁷ Subsequent experience demonstrated that chemoradiotherapy was curative in most patients, and the subsequent APR has been abandoned unless the tumor persists or recurs.

The reported experience with multimodality treatment for anal carcinoma continues to expand.^{37,42} The radiotherapy entails 30 to 60 Gy (given over 3 to 5 weeks) using apposed fields. Chemotherapy is given at the same time as the radiotherapy according to the following scheme: 5-FU (1,000 mg/m²/day) on days 1 to 5 and days 31 to 35 and mitomycin C (15 mg/m²) on day 1. Using an anoscope, the lesion site is inspected 4 to 6 weeks after the radiotherapy is completed, and a biopsy is performed on any abnormalities. Some providers will allow additional time after therapy to confirm complete clinical regression of the tumor before embarking on additional therapy. An APR, local excision, or additional chemoradiotherapy is offered to patients with residual disease following combined therapy.

Melanoma

Anorectal melanomas are rare; they account for 1% of all melanomas and 0.25 to 1% of anorectal tumors.⁴³ The mean age at occurrence is in the fifth decade; females are affected more frequently than males. The most frequent presenting symptom is bleeding, followed by an anal mass or pain. The lesions are usually elevated, and 34 to 75% will be pigmented.

These tumors are locally invasive and have a high metastatic potential. Because many patients present late, the reported 5-year survival rates range from 0 to 12%. The prognosis is related to tumor size, thickness, and clinical stage. Evaluation should include a biopsy and a search for metastatic disease (by CT of the abdomen, pelvis, and chest; liver function tests; chest x-ray evaluation; and bone scans). Special stains or electron microscopy may be required to confirm the diagnosis.

Surgery provides the only hope for cure. However, the small chance for cure and limited experience have led to controversy about the appropriate procedure. An APR has significant morbidity and mortality. Local excision has less associated morbidity. Reports have shown little difference in the mean survival rates following either procedure. Prophylactic lymphadenectomy is not indicated for clinically negative nodes but is helpful for clinically suspicious nodes. Radiotherapy and chemotherapy have demonstrated little benefit in this disease.

ANAL MARGIN

Premalignant Lesions

Premalignant lesions of the anal margin are uncommon and include Bowen disease and Paget disease. Bowen disease is an intraepithelial squamous cell carcinoma, and a few hundred

cases have been reported in the literature.⁴⁴ Paget disease is an even rarer intraepithelial adenocarcinoma, with approximately 300 cases of perianal disease reported in the surgical literature.⁴⁵ Patients with perianal Bowen or Paget disease commonly present with nonspecific complaints of anal itching, burning, or bleeding. Examination of the perineum in symptomatic patients usually reveals raised, irregular, scaly, brownish-red plaques with eczematoid features in perianal Bowen disease. In Paget disease, the lesions are well-demarcated eczematoid plaques that are either ulcerative and crusty or papillary. Less commonly, these lesions may have a gross appearance similar to that of other diseases (e.g., leukoplakia, squamous cell cancer, condylomata acuminata, dermatitis, eczema, downward spread of rectal carcinoma, or prolapsed hemorrhoids), making the diagnosis by inspection alone difficult. A significant percentage of patients will be diagnosed after pathologic evaluation of operative specimens.

The microscopic appearance of these perianal lesions is characteristic and readily confirms the diagnosis. An accurate diagnosis is important for prognostic and therapeutic reasons. The clinical course of Bowen disease has been relatively benign, with progression toward invasive carcinoma in 2 to 6% of cases. The incidence of subsequent nonsquamous malignancy is low. In Paget disease, progression into an invasive carcinoma has been reported to be as high as 40% in untreated lesions.⁴⁵ The incidence of associated malignancies in the reported series averaged 50 to 73%, and the mortality was high from this cancer despite aggressive therapy. The small number of reported patients with these perianal lesions has limited our understanding about prognosis.

Patients with Bowen disease are younger (average age 48 years) than those with Paget disease (average age 66 years). The sex distribution is equal for Paget disease patients, whereas in Bowen disease, there is a higher proportion of women. The incidence of an associated invasive malignancy is higher with Paget disease, and the prognosis is worse.⁴³

Patients with anal lesions that appear suspicious or fail to respond to conventional therapy within a month should undergo a biopsy. An adequate biopsy is essential both to confirm the diagnosis and to exclude an invasive carcinoma. A proper biopsy technique entails three or four full-thickness biopsies (i.e., including subcutaneous tissue) from the central portion and edges of the lesion. This can be easily accomplished with local anesthesia, a sharp punch biopsy, and fine-pointed scissors or a scalpel. If pathologic evaluation identifies a premalignant or potentially malignant lesion, the patient should undergo an evaluation to exclude an associated invasive cancer.

If evaluation demonstrates an invasive carcinoma without metastases, an aggressive approach is warranted to improve the historically poor prognosis associated with these diseases. For adenocarcinoma of the lower rectum, the author recommends an APR, and for an epidermoid anal cancer, chemoradiotherapy is suggested.

In the absence of invasive cancer, a local excision with clear margins has been recommended. The wound defect is either closed primarily, covered with a split-thickness skin graft (either at the initial operation or 3 to 4 days later), or allowed to heal by secondary intention. Wide excision of lesions, especially very large ones, can produce significant morbidity.

Therefore, the morbidity of large, wide excisions must be balanced against the low incidence of cancer development in patients who are monitored closely. In selected patients, the author currently recommends excision of gross lesions, followed by close follow-up.⁴⁶

Long-term follow-up is recommended to prevent recurrence of both perianal Bowen and Paget disease. However, the limited experience with this disease has hindered the development of a standardized follow-up regimen. An annual complete physical examination, proctosigmoidoscopy, and punch biopsy of any new lesion are performed. If a recurrence is found, it is excised with adequate clear margins using the methods described above.

Malignant Lesions

Squamous cell carcinoma of the anal margin acts in a manner similar to that of lesions occurring in other cutaneous areas of the body. The lesions appear as raised, hard, flat masses that may ulcerate. The appropriate therapy is wide local excision with clear margins.

Basal cell cancers of the anal margin are rare and appear as ulcerated masses. Nonspecific complaints include bleeding and pruritus. Wide local excision with clear margins is the treatment of choice.⁴⁶

Retrorectal Tumors

The retrorectal space is bounded by the rectum anteriorly, the sacrum and investing sacral fascia posteriorly, and the ureters, internal iliac arteries, and rectal stalks laterally.⁴⁴ The space extends cranially to the peritoneal reflection. Various classification schemes have been reported for retrorectal tumors. Most commonly, these tumors are broadly categorized as inflammatory, congenital, neurogenic, osseous, and miscellaneous [see Table 3]. Others have proposed benign versus malignant and congenital versus acquired.⁴⁷ With improved preoperative imaging and the widespread use of colonoscopy, most modern series exclude metastatic and/or locally advanced colorectal and genitourinary carcinomas from the category of retrorectal tumors. Likewise, inflammatory conditions that mimic primary tumors can usually (although not always) be diagnosed prior to surgical exploration. The most common or unique retrorectal tumors are discussed below.

LESIONS

Developmental Cysts

These lesions result from abnormal closure of the ectodermal tube (dermoid and epidermoid cysts) or sequestration of the developing hindgut (enterogenous cysts and cystic hamartomas).⁴⁸ Developmental cysts are always lined with epithelium, either squamous epithelium with (dermoid) or without (epidermoid) skin appendages or cuboidal, transitional, or columnar epithelium (enterogenous cysts and cystic hamartomas). Most often they are multilocular, and disorganized smooth muscle fibers can be identified surrounding their thin walls. The more common developmental cysts include dermoid, epidermoid, and enterogenous cysts (rectal duplication cysts). These lesions are usually benign and more common in females.

Table 3 Differential Diagnosis of Retrorectal Tumors

Congenital
Developmental cyst (epidermoid, dermoid)
Cystic hamartoma (rectal duplication)
Teratoma
Teratocarcinoma
Chordoma
Adrenal rest tumor
Anterior sacral meningocele
Inflammatory
Perineal or pelvirectal abscess
Endometriosis
Foreign body granuloma
Infectious granulomas
Diverticulitis
Crohn disease
Neurogenic
Neurofibroma
Neurilemoma
Ependymoma
Ganglioneuroma
Neurofibrosarcoma
Osseous
Osteoma
Osteogenic sarcoma
Ewing tumor
Chondromyxosarcoma
Giant cell tumor
Aneurysmal bone cyst
Miscellaneous
Metastatic carcinoma
Lipoma/liposarcoma
Hemangioendothelial sarcoma
Extra-abdominal desmoid
Plasma cell myeloma
Fibrosarcoma
Leiomyoma/leiomyosarcoma
Hemangioma
Endothelioma
Pelvic ectopic kidney

Teratoma and Teratocarcinoma

By definition, teratomas contain cellular elements derived from all three germ layers. They originate from totipotential cells that are abnormally sequestered during in utero development. Although the sacrococcygeal area is the most common

site for teratomas in newborns, de novo lesions in this region are rare in adults. Teratomas are classified as mature, immature, or malignant (teratocarcinoma). Mature teratomas contain recognizable epithelial and/or mesenchymal cells, whereas immature tumors are composed of primitive endoderm, mesoderm, or ectoderm. Malignant teratomas contain neoplastic cells of germ cell origin (e.g., choriocarcinoma, germinoma), as opposed to teratomas with malignant transformation, which contain malignant cells of somatic origin that have presumably degenerated. Only 4% of teratomas diagnosed at birth are malignant, whereas those found later in childhood tend to be very aggressive and associated with a poor prognosis.⁴⁹ Approximately 30% of adult teratomas harbor malignancy at the time of resection.

Chordoma

Chordomas arise from remnants of the embryologic notochord, a primitive streak running from the skull base to the pelvis and represented by the nucleus pulposus in normal adults. These are rare bony tumors, but approximately 50% of all chordomas are located in the pelvis and retrorectal space. They are the most common malignant tumor of this region. Chordomas are lobulated, gelatinous tumors that tend to be slow-growing but locally destructive. Intratumoral hemorrhage can create a cystic appearance, and a pseudocapsule is commonly present. The pathognomonic feature on microscopy is the presence of “physaliferous” cells, which are vacuolated and filled with mucous droplets. Although they may occur at any age, chordomas typically present in the sixth and seventh decades and are much more common in men.⁵⁰ Despite the rare tendency to metastasize, chordomas are difficult to treat for cure. Symptoms are typically delayed until the tumor reaches a large size, making resection with uninvolved margins extremely difficult.

Anterior Sacral Meningocele

These rare tumors consist of a congenital herniation of the dural sac through the sacrum. The lesions are commonly associated with other developmental abnormalities, such as spina bifida, tethered spinal cord, and genitourinary tract malformations. The sac communicates with the spinal canal and is filled with cerebrospinal fluid. Symptoms result either from local compression of other organs (e.g., the rectum, producing constipation) or by straining maneuvers causing sudden increases in the intracranial pressure (e.g., onset of headache with bowel movements). Treatment involves ligation of the neck of the dural sac prior to resection and typically can be accomplished through a posterior approach. Large anterior meningoceleles require an anterior approach with resection of the tumor followed by closure of the dural sac.

Neurogenic and Osseous Tumors

Tumors arising from pelvic nerve roots, peripheral nerves, or primary bony tumors can occur in the retrorectal space. Taken together, neurogenic and osseous tumors comprise between 20 and 30% of primary retrorectal tumors.⁵⁰ Two thirds of neurogenic tumors in this region are benign; however, even benign tumors that arise from the spinal cord can

produce devastating neurologic morbidity. The most common malignant neurogenic lesions are neuroblastomas, schwannomas, and ependymomas, whereas benign tumors include neurilemmomas and ganglioneuromas. Osseous tumors can derive from cartilage, bone, or fibrous tissue. They behave similarly to bony tumors in other anatomic locations, with sarcomas having a predilection for hematogenous spread to the lungs.

Miscellaneous

Carcinoid tumors of the retrorectal space are rare but have been described. Most represent direct extension or metastatic spread from rectal carcinoids. Retrorectal carcinoid tumors may also arise from the glandular cells present in rectal duplication or tailgut cysts.⁵¹ These lesions are potentially malignant and should be treated by local excision, typically using a perineal approach.

CLINICAL PRESENTATION

Retrorectal tumors are frequently asymptomatic, and they are often found incidentally during evaluation for unrelated physical complaints. Furthermore, even patients with symptoms directly referable to a retrorectal tumor may be initially misdiagnosed as having fistulae in ano; pilonidal cysts; perianal abscesses; psychogenic, posttraumatic, or postpartum pain; or proctalgia fugax. Patients may initially complain of constipation, paradoxical diarrhea, and frequent urge to defecate as the tumor causes compression of the adjacent rectum or pain (either pelvic discomfort or sciatic symptoms). Malignant tumors that invade the sacral plexus or nerve roots can lead to bowel and bladder incontinence or urinary retention.

In most cases, these lesions are palpable on digital rectal examination.⁵² The presence of a postanal skin dimple is suggestive of a developmental cyst. Most retrorectal tumors will feel soft and compressible, whereas teratomas may contain abnormal calcifications that are palpable. A tender mass is suggestive of either an infected developmental cyst or a primary perirectal abscess with supralelevator extension.

All patients with suspected retrorectal tumors should undergo complete colonoscopy. The rectal mucosa overlying a retrorectal tumor will appear normal, and larger lesions will demonstrate extraluminal compression of the rectum.

EVALUATION

Plain radiographs of the pelvis are typically normal unless a malignant tumor has produced bony destruction of the sacrum or rare, benign, bone-based lesions such as aneurysmal bone cysts, giant cell tumors, and osteochondromas are present. Teeth or small bone fragments may be visible in presacral teratomas. The “scimitar sign” (a concave sacral deformity suggestive of the curved sword) is characteristic of anterior sacral meningocele. Normal transrectal ultrasonography (TRUS) performed by an experienced surgeon effectively rules out a retrorectal tumor.

CT or MRI is the standard for the preoperative evaluation of retrorectal tumors. Either modality will demonstrate whether the lesion is cystic or solid and the extent of the lesion, but radiologists have difficulty in differentiating benign from malignant lesions.⁵⁰ Sixty percent of solid tumors are

malignant, whereas 90% of cystic lesions are benign. Thus, although certain characteristics on imaging may be suggestive of a benign pathology, imaging alone cannot obviate the need for surgical resection.

TREATMENT

In appropriate surgical candidates, all retrorectal tumors should be resected, even if asymptomatic.⁴⁸ A multidisciplinary approach involving colorectal surgeons, neurosurgeons, and possibly orthopedists is important. In general, preservation of at least unilateral S3 nerve roots typically allows normal bowel and bladder function following sacral resection.⁵¹ The surgical approach is based on preoperative imaging and expected extent of resection.

Biopsy of a retrorectal tumor prior to surgical resection should be avoided. Transrectal biopsy can lead to superinfection of cystic lesions, produce rapidly fatal meningitis in patients with anterior sacral meningocele, and seed needle tracts.⁴⁸

Perhaps the only indication for biopsy is to make a diagnosis in the patient who is not a candidate for surgery but may benefit from palliative radiation or chemotherapy.

Abdominal- or Perineal-Only Approaches

The perineal-only approach is typically reserved for smaller retrorectal tumors that lie mostly caudal to the S4 level, which are typically palpable on digital rectal examination. An abdominal-only approach may be used for high retrorectal tumors that do not involve the sacrum and lie above S4; however, most large lesions are best treated with a combined abdominoperineal approach, as discussed below.

For the perineal approach, the patient is placed in the prone jackknife position with the buttocks retracted laterally with tape. Either a transperineal or parasacral incision may be used. After the incision is made and muscular attachments to the coccyx and lower sacrum are divided, the coccyx can be dislocated and resected to facilitate further exposure and resection.

Once the coccyx has been disarticulated, the presacral space is readily accessible, and dissection of the tumor from the posterior wall of the rectum can proceed. Alternatively, further sacral disarticulation can be performed as needed. Extensive involvement of the rectal wall can necessitate en bloc proctectomy. Following tumor excision, a closed suction drain is placed in the retrorectal space and the muscles are reapproximated. For large tumors, closure of the pelvic floor with a gluteal flap (often in conjunction with a plastic surgeon) can aid in filling the residual tissue defect.

Combined Abdominoperineal Approach

For the combined approach, the procedure begins with the patient in either the supine or the modified lithotomy position, and the abdomen is opened using a low midline incision. The sigmoid colon is mobilized medially, and the inferior mesenteric artery is identified. Both ureters and the hypogastric nerves are also identified, swept laterally, and preserved. The retrorectal space is entered by incising the peritoneum in the posterior midline at the sacral promontory. The areolar plane between the mesorectal fascia and presacral fascia is

then sharply dissected, proceeding caudally until the tumor is encountered. The middle sacral vessels can be ligated, as can branches from the hypogastric arteries, to gain vascular control of the tumor and reduce bleeding during the deeper portions of the pelvic dissection and the subsequent perineal phase of the operation. The upper aspect of the tumor is then carefully dissected from the surrounding structures, typically, the presacral fascia posteriorly, the levators laterally, and the posterior wall of the rectum anteriorly. If the tumor is adherent to the rectum, an en bloc proctectomy should be performed, with most patients able to undergo restoration of intestinal continuity by coloanal or low-colorectal anastomosis. Once vision becomes limited in the deep pelvis and accurate planes of dissection can no longer be defined, the abdomen is closed, and the patient is either repositioned in

the prone jack-knife position or left in the modified lithotomy position for the perineal phase of the operation, which then proceeds as previously described. If en bloc proctectomy has been necessary and the resection completed in the prone jackknife position, the patient can be returned to the modified lithotomy position for creation of the anastomosis.

Adjuvant Therapy

The rarity and heterogeneity of retrorectal tumors make it difficult to demonstrate the efficacy of adjuvant treatment. Radiation therapy may have a role in palliation of unresectable presacral tumors.

Financial Disclosures: None Reported.

18 UPPER GASTROINTESTINAL ENDOSCOPY

*Jeffrey Marks, MD, FACS, and Jeffrey L. Ponsky, MD, FACS**

Since the beginning of the 1970s, flexible endoscopy of the gastrointestinal tract has been the dominant modality for the diagnosis of gastrointestinal disease. Over the same period, developments in technology and methodology have made possible the use of endoscopy to treat a host of conditions that once were considered to be manageable only by means of open surgical procedures. The concept of performing endoscopic surgery has become a reality with the advancement of endoscopic therapies to perform mucosal ablation, resection, and tissue approximation. In addition, investigation into intra-abdominal therapy has begun with the progression of natural orifice transluminal endoscopic surgery (NOTES). The tools created for both intraluminal and transluminal interventions will allow the endoscopist to continue to supplant surgical therapies for numerous gastrointestinal diseases. The integration of flexible endoscopic techniques into the armamentarium of the gastrointestinal surgeon permits a more multidimensional approach to the treatment of digestive disease. The modern surgeon must continue to stay abreast of these endoscopic advances to provide appropriate patient care.

Endoscope History

The flexible endoscope was initially developed in 1957 as an imaging device dependent on the delivery of light and transmission of the image along multiple bundles of chemically treated glass fibers. The image undergoes a series of internal reflections within each fiber, which are coated with low optical density glass to prevent escape of light as it is transmitted up the bundle. The endoscopist views the image through an eyepiece at the top of the instrument handle.¹ A teaching head could be fixed onto this eyepiece, allowing a second person to view the endoscopic image. With the advancement of early video camera systems, a video camera could be affixed to the scope eyepiece to transmit an image to a video monitor. Eventually, the video system was imbedded into the scope, allowing the progression from fiberoptic scopes to the videoendoscopes we use today. This has been the key component in the advancements in our ability to perform more involved therapies, educate physicians and endoscopic assistants, and obtain static and dynamic recorded data images for improved clinical management.

* The authors and editors gratefully acknowledge the contributions of the previous author, Alicia Fanning, MD, to the development and writing of this chapter.

Endoscope Structure

Although the basic structure of the endoscope is unchanged, there are now a wide variety of lengths and diameters of scopes, with an assortment of channel numbers and sizes and adjunct imaging modalities. By knowing the differences among available scopes, the skilled endoscopist is better able to match his or her tools to the desired procedure. The knobs for controlling scope tip manipulation are located on the right side of the headpiece and provide quadridirectional movement. The inner control knob is for up/down and the outer knob for left/right. The two buttons on the front of the scope provide lens cleaning, air insufflation, and suction.

The suction channel also functions as the biopsy channel so that any endoscopic tools placed into the biopsy channel will limit the ability to suction fluids through the endoscope. A small button on the front of the handpiece above the suction button allows for freezing of the image and digital recording by pressing the image capture button on the back of the handpiece.

Advancements in Imaging Technology

There have been many recent advances in endoscopic imaging techniques with the goal of improving immediate detection of dysplasia and other mucosal abnormalities. The ability to perform an “optical biopsy” at the time of the endoscopic procedure would enhance directed tissue sampling and resection as well as overall endoscopic therapy. It should be noted that these techniques can be used for both upper and lower endoscopic procedures.

CHROMOENDOSCOPY

This technique is based on the staining of mucosal surfaces to differentiate different cellular activities and subtle mucosal abnormalities. Liquids commonly used as topical mucosal agents include Lugol (potassium iodide) solution, methylene blue, indigo carmine, and Congo red. Diseases, including Barrett esophagus and squamous cell carcinoma of the esophagus, have been detected with the use of Lugol solution. Normal keratinized squamous epithelium stains a deep brown as a result of a reaction between the potassium iodide and glycogen, but inflammation, dysplasia, and carcinoma do not stain because of a lack of glycogen. Staining of the esophagus with methylene blue may be useful in the search for Barrett mucosa: the blue dye is avidly absorbed by the intestinal absorptive cells of the columnar epithelium. Darkly stained areas may be biopsied for confirmation.²

NARROW-BAND IMAGING

Most endoscopes now have the ability to switch the bandwidth of projected light just by pressing a button on the scope handle. Narrow-band imaging (NBI) can differentiate squamous from nonsquamous epithelium to help identify Barrett esophagus [see *Figure 1* and *Figure 2*]. The use of white light as well as NBI has also enabled endoscopists to provide an immediate assessment of small colonic and gastric lesions without histopathologic evaluation.³

OPTICAL COHERENCE TOMOGRAPHY

This technique uses reflection of near-infrared light to produce real-time two-dimensional cross-sectional images of the gastrointestinal tract. A small probe similar to an endoscope ultrasound probe that does not require tissue contact is passed through the scope. Optical coherence tomography produces a high-resolution image of the layers of the gastrointestinal

Figure 1 The squamocolumnar junction seen with routine white light.

Figure 2 The squamocolumnar junction as seen with narrow-band imaging.

tract. Although not yet in widespread use, investigation into the accurate identification of diseases such as Barrett esophagus is ongoing.

Basic Upper Endoscopy

INDICATIONS

Upper endoscopy, or esophagogastroduodenoscopy (EGD), is indicated when a patient has abnormal findings on traditional gastrointestinal x-ray series or one of the “alarm symptoms,” such as weight loss, early satiety, hematemesis, dysphagia, odynophagia, epigastric pain that does not respond to medical therapy, persistent heartburn, suspected foreign body, or iron deficiency anemia. It is also indicated for surveillance of patients at high risk for malignancy and for sampling of gastrointestinal tissue or fluid. Unsedated transnasal endoscopy with slim endoscopes can also be performed in patients with suspected esophageal or gastric pathology. Biopsies can be performed, but no therapeutic interventions can be provided because of the limitation of the biopsy channel.

CONTRAINDICATIONS

Contraindications to EGD include underlying patient comorbidity and inability to tolerate conscious sedation. Recent surgery or anastomosis is not a contraindication to an EGD, and the risks and benefits of any procedure must be weighed before proceeding.

ASSESSMENT AND MONITORING

Following initial patient evaluation, including American Society of Anesthesiologists classification and Mallampati scoring to assess risk for airway compromise, the patient is placed in a left-side-down decubitus position. One prepares for the examination by ensuring the patient’s hemodynamic stability, having the patient fast for 6 to 8 hours beforehand, and then proceeding with the delivery of medications to provide conscious sedation, which generally involves applying a topical anesthetic to the posterior pharynx and administering a narcotic and a benzodiazepine intravenously. Monitoring of arterial blood pressure and oxygen saturation throughout the procedure is now standard practice.

TECHNIQUE OF UPPER ENDOSCOPY

With the patient in the left lateral decubitus position, a topical anesthetic may be applied to the posterior pharynx and an intravenous sedative administered. The forward-viewing panendoscope—a small-caliber instrument that is long enough to permit examination of the foregut from the mouth to the third portion of the duodenum—is employed. The endoscope is held in the left hand regardless of the individual physician’s hand dominance. The internal upward and downward deflection knob is controlled by the left thumb while the air, water, and suction knobs are controlled by the left index and middle fingers. The smaller left/right knob then is usually manipulated by the right hand.

The endoscope should be introduced under direct visualization rather than using two-handed techniques, which increase the risk for both the patient and the physician. The instrument is advanced slowly until the epiglottis and vocal cords are visualized [see *Figure 3*]; it is then angled posteriorly

Figure 3 Normal appearance of the vocal cords and arytenoid cartilages.

to the esophageal introitus and gently advanced as the patient is asked to swallow. Insufflation of air is begun to distend the esophagus, which appears as a long, round tube. Frequent peristaltic waves are seen; these are normal. Mucosal surfaces must be closely inspected for signs of ulceration, stricture, tumor, or Barrett (columnar) epithelium, which manifests itself as orange patches in otherwise pale salmon-pink esophageal (squamous) mucosa. When abnormalities are noted, biopsy, brushing for cytologic evaluation, or both should be performed [see Figure 4]. As the endoscope is advanced, insufflation is continued, and the curve of the lumen is followed to the left as the esophagus traverses the diaphragm to enter the stomach. If the lumen is not fully visualized, the endoscope is withdrawn and the examination resumes. The distance from the incisors to the esophagogastric junction must be identified and recorded. The diaphragmatic incursion is next identified as it “pinches” on the esophageal lumen. Increased length between these two markers is classic

Figure 4 Evidence of severe *Candida* esophagitis.

for sliding or type I hiatal hernia, as is the presence of gastric folds above this pinched area. The pinching may be better visualized when the patient sniffs.

When the stomach is entered, the tip of the endoscope is elevated so as to center it within the gastric lumen. It should be noted that with the patient lying in the left lateral decubitus position, the stomach is also on its side, with the greater curvature at 6 o'clock, the lesser curvature at 12 o'clock, the posterior wall at 3 o'clock, and the anterior wall at 9 o'clock. Air should be insufflated to distend the stomach fully and permit careful inspection of all mucosal surfaces [see Figure 5 and Figure 6].

After the stomach has been viewed, the instrument is advanced under direct vision through the pylorus and into the duodenal bulb. Insufflation of air should continue as the scope is pressed against the pylorus to facilitate passage of the instrument [see Figure 7]. The scope tends to pop into the duodenal bulb rather than slide smoothly; it should be pulled

Figure 5 Esophagogastroduodenoscopy revealing linitis plastica of the stomach.

Figure 6 Esophagogastroduodenoscopy revealing a small, nonbleeding, gastric ulcer.

Figure 7 Normal-appearing pylorus and antrum.

back slightly to allow one to observe the mucosal surfaces of the bulb before moving ahead. Unlike the rest of the small bowel, the duodenal bulb has no semicircular folds [see Figure 8]. The tip of the scope must be rotated slightly to permit examination of the walls of the bulb. It is advisable to pull the instrument back into the stomach while observing the walls of the bulb and the pyloric channel for lesions; several such withdrawals may be required for full assessment of this area.

Once the duodenal bulb has been examined, the endoscope is advanced just past the bulb to the point where the first duodenal folds are observed. Here, the duodenum turns sharply to the rear and downward as it becomes retroperitoneal. Advancement of the scope into the second portion of the duodenum is one of the few endoscopic maneuvers that cannot be accomplished under direct vision [see Figure 9]. Because of the sharp angle of the turn, one will experience a moment of so-called “red-out” as the tip of the endoscope touches the mucosa during the turn. To ensure that the

Figure 8 Normal appearance of the duodenal bulb.

Figure 9 Normal appearance of the second portion of the duodenum. The major papilla is seen at the 9 o'clock position, along the medial wall of the duodenum.

turn is accomplished safely, the instrument is advanced as far through the bulb as is possible under direct vision. The control handle of the scope is then rotated approximately 90° to the right as the tip of the scope is turned to the right and angled first upward and then downward. As the second portion of the duodenum appears, the scope is rotated back to its neutral position. When done correctly, the turn is actually quite easy. It should never be forced: if the instrument does not proceed easily into the descending duodenum, the scope should be pulled back and the attempt repeated. Pushing against resistance may result in perforation.

Entering the descending duodenum causes the scope to form a large loop in the stomach. Therefore, once the second portion of the duodenum is successfully entered, the shaft of the instrument is pulled back. Paradoxically, as this movement straightens the gastric loop, it also advances the tip of the instrument deeper into the duodenum. Further advancement of the instrument under direct vision often permits entry into the third or even the fourth portion of the duodenum. Once the distal limit of intubation is reached, the scope is withdrawn and the luminal surfaces are carefully examined. Rotating the scope with small right-left movements of the controls and side-to-side movements of the control handle itself will help demonstrate the more subtle details of duodenal anatomy. The endoscope is then withdrawn back into the gastric lumen and full upward deflection is performed as the scope is inserted. This allows a retroflex view of the cardia and fundus [see Figure 10]. Often the upper gastrointestinal tract is inspected more completely while the instrument is being withdrawn than while it is being advanced.

COMPLICATIONS OF DIAGNOSTIC EGD

Complications of diagnostic EGD are divided between those related to the actual performance of the procedure and those related to the delivery of conscious sedation. Perforation secondary to EGD can occur related to scope tip or elbow trauma, or barotrauma, which is the insufflation of air. In the cervical esophagus, anatomic alterations such as Zenker

Figure 10 Retroflex view of the gastric fundus. The angularis is seen at the 2 o'clock position along the lesser curvature.

diverticulum, vertebral osteophytes, and cervical ribs can contribute to the occurrence of perforation. Cervical esophageal perforation can usually be managed conservatively with observation and antibiotics but rarely requires cervical drainage of abscess formation. Perforation of the mid- or distal esophagus is very rare with diagnostic EGD. In the stomach and duodenum, perforation is also very rare. Other rare complications include bleeding and infection.

The delivery of conscious sedation can lead to cardiac and pulmonary complications. The presence of an endoscope across the upper esophageal sphincter can increase the risk for airway compromise and aspiration. Cardiac events such as arrhythmias and hypotension are usually the result of primary respiratory compromise such as hypoventilation and resultant hypoxia.⁴ Oxygen saturation is closely monitored throughout the procedure, and if there is a noticeable drop, jaw thrust, increased supplemental oxygen, and verbal communication can all be used to improve the patient's respiratory status. If this is not effective, the procedure should be aborted immediately with scope removal and consideration given to delivery of reversal agents. Appropriate drugs must always be readily available to reverse sedative effects, and a suction apparatus must be ready for use at all times.

Therapeutic Esophagogastroduodenoscopy

ENDOSCOPIC TISSUE SAMPLING

Sampling of tissue is most frequently obtained by passage of a spiked forceps via the endoscope's biopsy channel. Multiple biopsies should usually be obtained. For ulcers, one should biopsy the edge of the lesion in at least four quadrants. Standard biopsy techniques are quite superficial; however, if deeper biopsies are desired, these can be obtained by using either a jumbo forceps or the practice of repetitive biopsies at the same site, which will lead to a deeper sampling. Tissue and lesions can also be sampled by the use of brush cytology.

ENDOSCOPIC TECHNIQUES FOR MANAGEMENT OF BLEEDING

Endoscopy plays a direct role in the evaluation and treatment of upper gastrointestinal bleeding (UGIB). The timing for endoscopy should be based on each individual clinical scenario, understanding that EGD has both a diagnostic and a therapeutic potential. Prior to EGD, the patient must be stabilized with transfusion of blood products for correction of anemia and coagulopathy as needed, and endotracheal intubation for airway protection if warranted. Techniques of providing endoscopic hemostasis can be divided into thermal and nonthermal categories. It is also possible to treat bleeding with combined modalities such as coagulation and injection or clipping and injection. Given the relatively high success rates of controlling UGIB by endoscopic means, it is appropriate to pursue EGD initially before considering surgical or interventional radiology options.⁵

Thermal Endoscopic Tools

Thermal therapies control hemorrhage by inducing tissue coagulation, collagen contraction, and vessel shrinkage. Thermal energy tools are divided between contact and noncontact categories. These techniques overall are easy to use, although perforation may occur with an extensive delivery of energy in areas of thinner viscus walls, such as the duodenum or cecum.

Contact thermal tools Contact or coaptive techniques involve the use of probes passed via the biopsy channel, which allow for pressure tamponade of the bleeding point with simultaneous application of thermal energy for coagulation. The firmer one applies the device to the tissue, the greater the depth of energy penetration. The heat generated, which can reach several thousand degrees, is sufficient to cause full-thickness tissue damage, so care is required when using this modality.

Noncontact thermal tools Energy delivered to the mucosal without direct contact is referred to as a noncontact thermal tool. Argon plasma coagulation (APC) is an example of this technique in which thermal energy is applied to tissue via ionized argon gas. The energy is actually "sprayed" rather than delivered via direct contact. APC is particularly well suited for settings where large mucosal areas require treatment, such as gastric antral vascular ectasia (GAVE), or where the risk of deeper thermal injury leading to perforation is of heightened concern, for example, in the duodenum or cecum⁶ [see Figure 11 and Figure 12].

NONTHERMAL ENDOSCOPIC HEMOSTASIS TOOLS

Injection Sclerotherapy

The delivery of hemostatic agents is performed by passage of a needle catheter system via the biopsy channel of the endoscope. The 5 mm needle can be advanced into the adjacent tissues and withdrawn as needed. The sclerosant agent is routinely injected submucosally at three or four sites surrounding a bleeding. The amount injected varies with different agents, and it must be remembered that systemic absorption will occur. The affect of hemostasis occurs secondary to direct tamponade and to vasoconstriction. Dilute

Figure 11 Esophagogastroduodenoscopy revealing gastric antral vascular ectasia.

1:10,000 epinephrine solution is the most commonly used agent and should be limited to less than 10 cc total volume. For esophageal varices, injections are begun just above the gastroesophageal junction. Sclerosants can be injected either directly into the varix or alongside it, intravariceal or paravariceal.

Endoscopic Band Placement

Endoscopic rubber band ligating devices can be used with most standard endoscopes and provide an alternative for management of variceal and nonvariceal bleeding. This technique is based on the ability to suction tissue into a cap placed at the tip of the endoscope and then, with the turning of a control knob, fire a small, tightly constricting rubber band. Applications for endoscopic banding include treatment of internal hemorrhoids, Dieulafoy ulcers, esophageal and

Figure 12 Appearance of gastric antral vascular ectasia following treatment with argon plasma coagulation.

gastric varices, and mucosal neoplasia in conjunction with endoscopic mucosal resection.⁷

Endoscopic Clip Placement

Endoscopic clip placement is an effective method to control bleeding and can be used safely at multiple sites throughout the gastrointestinal tract in conjunction with other endoscopic therapies. The clips are created with different characteristics but routinely provide only a very superficial tissue approximation. The clips will usually slough off within 2 weeks and pass spontaneously through the gastrointestinal tract.⁸

Endoscopic Loop Placement

Pretied endoscopic loops can also be applied through a standard endoscope biopsy channel and can be used for ligation of pedunculated structures before or after endoscopic resection. These single-application devices are similar to laparoscopic endoloops, although they are nylon sutures, and instead of an actual slip knot, a plastic cinching device holds the loop in place once deployed.

ENDOSCOPIC DILATION TECHNIQUES

Endoscopic dilation can be performed for any enteral stricture that can be reached by endoscopic means. Stenoses and anastomotic strictures secondary to ischemia, inflammation, radiation, and neoplasm are all amenable to endoscopic dilation. The use of fluoroscopy as an adjunct to endoscopic dilation is believed to decrease the risk of perforation, although this has not been fully proven in randomized prospective trials. The two most common dilators available are the guide wire–driven type, which applies both axial and radial forces, and the balloon type, which applies only radial forces. Fluoroscopic guidance allows the endoscopist to gauge several components of the procedure. First, it ensures the positioning of the balloon or the guide wire in the viscus lumen. Second, if contrast is injected in the balloon as the dilating fluid, expansion of the balloon can be fully appreciated. This is termed “waist ablation” and refers to the full dilation of the balloon at the site of the stricture [see Figure 13 and Figure 14]. Fluoroscopy also can monitor the position of the guide wire as Savary-type dilators are advanced over the wire in a trolley system fashion. Long, complex strictures may be less responsive to endoscopic dilation, and many strictures may also require repeat treatments. Aggressive biopsying of the mucosa after dilation is necessary in cases of unclear etiology. Complications secondary to endoscopic dilation include bleeding, perforation, mucosal tears, and recurrent structuring.

ENDOSCOPIC ENTERAL STENT PLACEMENT

Endoscopic stents can be used for the treatment of strictures, leaks, fistulae, and obstructing neoplasms. The delivery system is dependent on the type of stent and the location for deployment. Endoscopic stent deployment is either through-the-scope (TTS) or wire guided using fluoroscopic guidance. TTS stents are delivered through the endoscope channel, are routinely a 10 French system, and require a therapeutic scope. Non-TTS stents are limited to the esophagus, including the esophagogastric junction or the rectosigmoid region. In patients following gastric resection, these systems can also traverse a gastrojejunostomy anastomosis.

Figure 13 Enteroscopy revealing small bowel stricture secondary to inflammatory bowel disease.

The characteristics of endoscopic stents are quite diverse, including different lengths, widths, and morphologies. In addition, stents can be uncovered, partially covered, or fully covered. Covered endoscopic stents have been created for the sole purpose of temporarily bridging esophageal and proximal anastomotic leaks and fistulae.⁹ These stents are considered removable as there is minimal tissue ingrowth, which occurs usually at the proximal and distal ends. The greatest problem with these stents is the high risk of migration. Bleeding, perforation, and obstruction are far less common complications.

Uncovered enteral stents, using TTS deployment systems, are not intended for removal and can be placed for temporary

Figure 14 Appearance of small bowel stricture following balloon dilation.

relief of benign and malignant strictures throughout the gastrointestinal tract.¹⁰ They are associated with tissue ingrowth and occasional occlusion if they are left in place, but they have a lower rate of migration. In unresectable disease states, palliation of obstruction with enteral stents can provide an alternative to surgical bypass procedures.

RETRIEVAL OF FOREIGN BODIES

Many ingested foreign bodies pass through the gastrointestinal tract uneventfully, but a good number must be removed by endoscopic means—in particular, foreign bodies in the esophagus, sharp objects that are likely to perforate the bowel, and objects that do not progress from the stomach.

If the ingested object is of an unfamiliar type, it is an extremely good idea to practice with a similar object outside the patient before attempting endoscopic retrieval. This preparatory step allows one to select the most appropriate accessory and technique for removing the object.

Technique

Objects with sharp edges should be removed with the sharp end trailing to prevent perforation. In some cases, this means that the object must be pushed into the stomach and turned around before being removed. If multiple foreign bodies are present or if it is highly likely that the foreign body will injure the esophagus if removed in the standard manner, an overtube should be placed over the scope before insertion. The overtube enables one to pass the instrument several times and retrieve any sharp objects without injuring the esophagus; it also helps ensure that the object is not aspirated into the airway. If the patient is a child or there is concern for airway compromise or aspiration, general endotracheal anesthesia may be advisable.

Multiple tools have been used for foreign-body extraction, including snares, nets, biopsy forceps, tripod forceps, suction caps, and baskets. Meat boluses that form in the esophagus or proximal to a gastric band may be extremely difficult to dislodge; the use of a variceal ligator cap to produce a suction chamber can be helpful in such situations. It is imperative to evaluate the site of foreign-body impaction after removal to rule out underlying pathology or resultant trauma, such as ischemic perforation.¹¹

Complications

Endoscopic removal of foreign bodies is extremely safe and effective. Care must be taken to ensure that the esophagus is not injured during removal of the object. If the object is deeply embedded or refractory to removal, a surgical approach is preferred.

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Since 1980, endoscopically guided placement of a tube gastrostomy has been widely employed to provide access to the gastrointestinal tract for feeding or decompression. Indications for percutaneous endoscopic gastrostomy (PEG) include various disease processes that interfere with swallowing, such as severe neurologic impairment, oropharyngeal tumors, and facial trauma. PEG has also been employed to establish a route for recycling bile in patients with malignant biliary obstruction, to provide supplemental feeding in selected patients with inflammatory bowel disease, and to

accomplish gastric decompression in patients with conditions such as carcinomatosis, radiation enteritis, and diabetic gastropathy.

Technique

The patient fasts for 8 hours beforehand, and a single prophylactic dose of an antibiotic is administered just before the procedure is begun. The patient is placed in the supine position, a topical anesthetic is applied to the posterior pharynx, and intravenous sedation is begun. A forward-viewing endoscope is passed into the esophagus and advanced into the stomach. The abdomen is prepared in a sterile fashion and draped. The stomach and the duodenum are then inspected.

The room lights are dimmed, and the light of the endoscope is used to transilluminate the abdominal wall so as to indicate a point where the gastric wall and the abdominal wall are in close proximity. Finger pressure is applied to various areas of the abdomen until a spot is identified at which such pressure produces clear indentation of the gastric wall. An endoscopic snare is deployed through the biopsy channel of the endoscope to cover this spot, and a local anesthetic is infiltrated into the overlying skin [see Figure 5]. A 1 cm skin incision is made at the chosen spot, and a needle is passed through the incision and into the gastric lumen. The endoscopic snare is tightened around the needle, and a wire is passed through the needle and into the gastric lumen. The snare is moved so as to surround the wire, which is then pulled out of the patient's mouth. The gastrostomy tube is fastened to the wire and pulled in a retrograde manner down the esophagus and into the stomach. The gastroscope is subsequently reinserted to ensure that the head of the catheter is correctly positioned against the gastric mucosa and there is no evidence of bleeding [see Figure 6].

An outer crossbar is put in place to prevent inward migration of the tube and to hold the stomach in approximation to the abdominal wall. The crossbar should remain several millimeters from the skin to prevent excessive tension, which would cause ischemic necrosis of the underlying tissue.

Complications

Local wound infections are the most common complications of PEG. They can be minimized by administering preoperative antibiotics and ensuring that excessive tension is not applied to the crossbar at the end of the procedure. When such infections do occur, they can usually be treated via simple drainage and local wound care; sacrifice of the gastrostomy is rarely necessary. Several other complications, such as early extrusion of the tube, progressive enlargement of the tract, and separation of the gastric and abdominal walls with leakage of feedings into the abdominal cavity, are also most often attributable to excessive crossbar tension and subsequent ischemia. Gastrocolic fistula can occur after PEG. This problem may not be obvious for months afterward, but severe diarrhea after feedings is grounds for suspicion. Once the PEG tract is mature, gastrocolic fistulae usually close quickly after simple removal of the gastrostomy tube.

PEG with Jejunostomy Tube Extension

In patients who fail to tolerate gastric feedings as a result of severe gastroesophageal reflux or gastroparesis, transpyloric

feeding can be provided via a jejunostomy tube passed through an existing PEG. PEG-J placement is achieved by passing a jejunal feeding tube through the PEG lumen (a 24 French PEG tube accommodates up to a 12.5 French J tube; a standard 20 French PEG tube accommodates an 8.5 French J tube). Endoscopically, the jejunal tube is guided into the duodenum under direct vision with either a biopsy forceps or an endoscopic clip.

DIRECT PERCUTANEOUS ENDOSCOPIC JEJUNOSTOMY TUBE

Feedings beyond the ligament of Treitz using direct percutaneous endoscopic jejunostomy (PEJ) are associated with a lower incidence of gastroesophageal-induced aspiration compared with simple postpyloric feeding but are associated with increased procedural risks, including bleeding, inadvertent viscus injury, and leakage.¹² Performance of direct PEJ requires both endoscopic and fluoroscopic guidance. Abdominal wall depression with a hemostat is performed at this site to try to identify a loop of small bowel adjacent to the abdominal wall. Safe tract techniques are then used to access the identified bowel, and a "pull" PEJ is performed with either a 16 French or a 20 French tube.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Endoscopic retrograde cholangiopancreatography (ERCP) is an advanced procedure that is technically more challenging than standard upper gastrointestinal endoscopy; however, it can be mastered by most endoscopists who are willing to dedicate sufficient time to learning the method. ERCP yields a radiologic image of the pancreatic and biliary trees and, in many cases, provides access for therapy. Indications for ERCP include suspected benign or malignant maladies of the common bile duct (CBD), the ampulla of Vater, or the pancreas. Cholelithiasis per se is not an indication for ERCP unless choledocholithiasis is suspected. Diagnostic ERCP is rarely performed because of the high risks of this procedure. MRCP provides safer radiographic imaging of the pancreaticobiliary trees.¹³ The therapeutic potential of ERCP is quite extensive and has supplanted surgical intervention for many diseases of the pancreas and biliary systems.

Technique

As with standard upper gastrointestinal endoscopy, the patient fasts for 6 to 8 hours beforehand. Intravenous sedation is administered, and prophylactic antibiotics are given when biliary obstruction is suspected. The patient is initially placed in the left lateral decubitus position but is later rotated to the prone position after the scope is in place in the second portion of the duodenum. A side-viewing endoscope is employed because it allows the best visualization of the ampulla of Vater. The instrument is passed into the esophagus and maneuvered through the stomach, across the pylorus, and into the duodenum.

Once the endoscope is in the second portion of the duodenum, it is pulled back so that the gastric loop is straightened and the tip of the scope occupies a better position with regard to the papilla. This so-called short scope position is generally best for work in the CBD. The papilla of Vater (also known as the major duodenal papilla) appears as a small, longitudinal nubbins crossing the horizontal semicircular folds of the duodenum, generally in the 12 to 1 o'clock position [see Figure 15].

At its tip, a small, soft, reticulated area may be noted; this is the papillary orifice. Often a small mucosal protuberance is seen just proximal and to the right of the papilla of Vater; this is the minor duodenal papilla.

A small plastic cannula is passed through the channel of the endoscope and introduced into the ampullary orifice, and contrast material is injected under fluoroscopic control to provide visualization of the CBD and the pancreatic duct. The two may share a single orifice within the ampulla or may have separate orifices. The CBD exits the papilla in a cephalad direction, tangential to the duodenal wall. The bulge of the ampulla within the duodenum represents the intramural segment of the duct. The orifice of the CBD is typically found at the 11 o'clock position in the ampulla. The pancreatic duct leaves the papilla in a perpendicular fashion. Its orifice is usually in the 1 o'clock area of the papilla.

Therapeutic interventions that may be accomplished at the time of ERCP include sphincterotomy for ductal access, sphincter of Oddi dysfunction, ampullary stenosis, removal of CBD stones, dilation of benign and malignant biliary strictures, and insertion of stents to maintain ductal patency [see Figure 16]. Pancreatic duct interventions include removal of stones, bridging of ductal disruptions, and drainage of pseudocysts.

All therapeutic applications of ERCP must begin with selective cannulation of the duct being treated. Frequently, a guide wire is then introduced deep into the duct to provide a means of obtaining access to the duct on an ongoing basis and to ensure correct positioning for intraductal manipulations. After electrosurgical division of the papilla, biliary stones are retrieved with balloons or baskets [see Figure 17]. Often

Figure 16 Electrosurgical division of the ampullary sphincter with a pull-wire sphincterotome.

large stones can be captured within the duct in mechanical lithotripsy baskets and crushed before removal.

Strictures should be brushed for cytologic evaluation once they have been traversed by a wire, although this carries a very low yield of sensitivity. They may then be dilated with

Figure 15 The appearance of the major papilla with a side-viewing endoscope. A periampullary diverticulum is seen and an endoscopic retrograde cholangiopancreatography catheter is selectively cannulating the common bile duct.

Figure 17 Following sphincterotomy, stone extraction is performed by withdrawing an extraction balloon.

hydrostatic balloons under fluoroscopic guidance and stented. Plastic stents are used for most benign and many malignant strictures; however, self-expanding metal stents are now being used more frequently for malignant strictures because they remain patent longer¹⁴ [see *Figure 18*, *Figure 19*, and *Figure 20*].

Figure 18 The appearance of a transpapillary positioned plastic biliary stent.

Figure 19 The appearance of a transpapillary positioned self-expanding metal biliary stent.

Figure 20 The appearance of a transpapillary positioned plastic pancreatic stent.

Complications

Perforation can occur during endoscopic sphincterotomy as a result of extension or tearing of the papilla beyond the junction of the CBD with the duodenal wall. Retroperitoneal or free intraperitoneal air may be seen. In many cases, intravenous antibiotics, hydration, and avoidance of oral intake are sufficient to manage such complications. If the patient's condition deteriorates, surgical exploration is indicated. Bleeding may also occur with endoscopic sphincterotomy at the time of the procedure or in a delayed fashion up to 1 to 2 weeks later. It is usually controllable at the time of the procedure with balloon tamponade, injection sclerotherapy, thermal coagulation, or endoscopic clip placement. If unsuccessful, interventional radiology may be able to provide embolization of the gastroduodenal artery to provide hemostasis.

Pancreatitis is the most common complication and can occur related to contrast injection with overfilling or acinarization of the ducts or rupture of the small ductules, with extravasation of contrast material into the pancreatic parenchyma; pancreatitis is a frequent consequence of acinarization. In addition, sphincterotomy and ampullary dilation are also associated with post-ERCP pancreatitis. Cholangitis may result when contrast is injected proximal to an obstruction of the biliary tree. When obstruction is demonstrated, drainage of the system by means of stone extraction, stenting, or nasobiliary intubation is important to prevent cholangitis.

DEEP SMALL BOWEL ENTEROSCOPY

The small bowel up until recently had been an elusive part of the gastrointestinal tract in terms of diagnostic and therapeutic endoscopic intervention. The advent of capsule endoscopy has permitted the endoscopist to obtain recorded

images of the lumen of the small bowel for identification of obscure sites of bleeding, inflammatory changes, and neoplasia, and more recently, specially designed endoscopes have allowed direct access to the entire small bowel via either an antegrade or retrograde fashion. Diagnostic and therapeutic small bowel procedures for processes such as bleeding, obstruction, and occult neoplasia have now been described using double-balloon endoscopy and single-balloon endoscopy. In addition, in select patients following surgical resection and reconstruction (i.e., Roux-en-Y bypass, long afferent limb), balloon enteroscopy can allow access into the desired segment of the small bowel.¹⁵

Both systems use the principle of scope fixation with a soft balloon that is serially inflated and deflated as the scope is advanced. This permits the endoscopist to pleat the bowel over the endoscope. The use of fluoroscopy is also helpful in guiding the endoscopist through the small bowel.

ENDOSCOPIC MUCOSAL RESECTION

The treatment of premalignant as well as superficial cancers can now be managed by endoscopic resective techniques. Endoscopic mucosal resection (EMR) has been employed for adenomas, dysplastic lesions, and early-stage carcinomas, including lateral spreading tumors. Multiple technical variations of EMR for the upper and lower tract have been developed, including submucosal injection, “suck-and-cut,” “suck-and-ligate,” and strip biopsy.

Saline Lift EMR

The most commonly performed EMR technique employs submucosal injection of a fluid followed by electrosurgical polypectomy. The most commonly used fluid is saline with or without epinephrine, although hyaluronic acid, glycerol, and dextrose have all been described. A bleb is created with the submucosal injection, creating space between the line of resection and the muscularis propria of the organ, and the lesion is resected. One caveat to this technique is that if the submucosal injection does not result in elevation, one must consider that this mass is an invasive lesion and should not be resected endoscopically.

“Suck-and-Cut” EMR

The “suck-and-cut” technique uses a specially designed cap attached to the tip of the endoscope. A submucosal injection may be created initially as with the saline lift EMR, and the lesion is sucked into the cap. A snare affixed inside the cap is used to encircle the lesion and is then resected by application of electrocautery similar to snare polypectomy. Similar to any thermal technique, the risk of perforation exists.

“Suck-and-Ligate” EMR

The “suck-and-ligate” technique transforms a sessile or nodular lesion into an artificial pedunculated polyp, which can then be resected with standard polypectomy techniques. A band ligating device is attached to the tip of the endoscope, the tissue is sucked into the cap, and a band is placed at the base of the lesion. This is done with or without saline lift injections prior to banding. The site is then resected with a snare similar to routine snare polypectomy.

The most frequent complications of EMR are bleeding and perforation. Immediate bleeding can be controlled

with endoscopically placed clips or injection of dilute epinephrine. Electrocautery should be used judiciously after EMR because the thin submucosa and serosa are susceptible to full-thickness injury with cautery. Delayed bleeding often requires repeat endoscopy with injection therapy or clip application, although angiography and embolization may be an alternative. Perforations can also be managed endoscopically with endoscopic clips as well as temporary enteral stent placement to cover the site of perforation.

ENDOSCOPIC SUBMUCOSAL DISSECTION

An extension of EMR that has been recently reported for endoscopic resection of more extensive lesions is endoscopic submucosal dissection (ESD). Using a combination of needle cautery and blunt endoscope cap dissection, large segments of tissue can be resected. The potential advantage of ESD is that it represents a more classic oncologic procedure compared with the piecemeal resection that occurs with other EMR techniques in that margins as well as lesion depth can be more accurately pathologically evaluated. Complications may be higher for ESD than for the other EMR techniques, including bleeding, perforation, and stricture formation.

ENDOSCOPIC MUCOSAL ABLATION

Endoluminal therapies for ablation of mucosal based diseases such as Barrett esophagus have recently seen great advances. Endoscopic radiofrequency ablation is a relatively new technology that has recently gained acceptance for treatment of intestinal metaplasia, as seen in Barrett esophagus.¹⁶ A balloon-based system, as well as a directed planar electrode device implementing this technology, has been used in this form of therapy. Several studies have proven feasibility and safety for this novel therapy, with very few documented cases of postprocedural structuring, as had been seen with photodynamic therapy. Further studies documenting the long-term effects of this therapy, as well as the absence of buried submucosal metaplastic glands or cancer, are still necessary.

ENDOSCOPIC ULTRASONOGRAPHY

The 1980s saw the introduction of endoscopic ultrasonography (EUS). Extracavitary ultrasonographic methods have been hampered by the presence of air within the gastrointestinal tract, which precludes high-resolution imaging. Consequently, they had been relegated to gross estimates of disease and detection of displacement of other tissues or fluid accumulation proximal to stenoses, such as ductal dilation in patients with CBD stones.

Three advances have proven invaluable in allowing EUS to carve out a niche in the field of gastrointestinal diagnosis. First is the improvement in endoscopes that allows transducer and receiver channels to traverse a tortuous path. Second is the development of multiple-frequency options in conjunction with circumferential visualization. Higher frequencies provide higher resolutions, allowing useful differentiation of the various layers of the intestinal tract. Third is the evolution of treatment protocols keyed to the accurate staging of tumors—information that is sometimes unobtainable from other imaging techniques.¹⁷

This technology has now been firmly established as an accurate way to identify carcinoma. More recent developments are allowing EUS to expand from the field of diagnosis

into the realm of intervention. Examples of EUS-guided procedures include fine-needle aspiration, lymph node sampling, and drainage of pancreatic pseudocysts.¹⁸

EUS devices come in both linear and radial transducers.¹⁹ Radial transducers have the advantage of providing circumferential visualization that parallels the standard modes of perceiving the gastrointestinal tract. Linear images allow EUS-directed biopsies and have the potential to provide color and pulsed Doppler imaging. Probes can be mounted on the top of an oblique-viewing fiberoptic scope or come in an over-the-wire format for use in the pancreaticobiliary tree. A series of frequencies are available, with the higher frequencies providing greater resolution but less tissue depth penetration. Lower-frequency probes allow deeper tissue assessment and a broader view, but at the price of reduced resolution. Nevertheless, any form of EUS will provide better resolution than transcutaneous ultrasonography, allowing markedly improved two-point discrimination and hence more accurate tissue diagnosis.

The benefits of accurate staging of gastrointestinal tumors paved the way for EUS development. Tissue sampling techniques are further benefited by this technology. The sensitivity of EUS makes it one of the best modalities for the evaluation and detection of pancreatic tumors. Its sensitivity, which is in excess of 95%, contrasts favorably with those of other modalities, including ultrasonography (75%), computed tomography (CT) (80%), and angiography (89%). The accuracy of T staging by EUS in esophageal cancer (80 to 90%) is greater than that of staging determined by CT scanning (50 to 60%). This finding has led to the development of several staging schemes that are based solely on EUS findings. EUS has established a role in the identification of early pancreatitis; the detection of CBD stones and mediastinal masses; and the assessment of anastomotic strictures, thickened gastric folds, and the integrity of the anal sphincter. It has also proved a useful adjunct in the determination of whether a tumor is amenable to EMR techniques or is better served by adjuvant therapies or surgical interventions.

The sensitivity of EUS is rooted in its ability to delineate the various layers of the alimentary canal. Experienced endoscopists can easily evaluate the submucosa and differentiate intramural from extrinsic masses. Characteristic patterns are readily learned and rapidly recognized, obviating tissue diagnoses in straightforward cases. Criteria have also been established to aid in the differentiation of benign and malignant lesions. With the continued use of this technique, additional algorithms will be established in conjunction with more

innovative interventional adjuncts. However, two limitations have caused many practitioners to remain skeptical: cost and training issues. Other imaging modalities, such as CT and magnetic resonance imaging, have also made tremendous strides recently. Although these various modalities are often considered competitors—a view arising from the perceived need for a single imaging modality—the issue of which is superior to the others pales in comparison with the benefits that can be gained from combining imaging techniques in appropriate circumstances.

Future of Endoscopy

The future in endoscopy will be based on advancements of both the tools and the applications available to endoluminal therapy. Intraluminal and transluminal endoscopic techniques are being proposed as potential surgical alternatives, taking on an increasingly more invasive and therapeutic role. Recent interest in NOTES united surgeons and gastroenterologists with the desire to access the abdominal cavity via naturally existing orifices, including the stomach, colon, bladder, and vagina.²⁰ An appropriate application for this approach is still yet to be elucidated. It is theorized that NOTES may have distinct advantages over laparoscopy in that NOTES may not necessarily require a sterile working environment to perform, and it possibly could also be completed under conscious sedation, similar to other endoscopic procedures.²¹

The obvious limitations to NOTES were based on the lack of adequate and appropriate endoscopic equipment. It was apparent early on that stable platforms would be necessary as well as endoscopic tools for cutting, hemostasis, and tissue manipulation. Transoral and transvaginal multichannel platforms with internal capability for manipulation and fixation are now becoming available. Scissors, suturing devices, bipolar forceps, and grasping devices are a few of the novel instruments soon to be added to the endoscopist's armamentarium.

These tools, however, will have a more likely impact on other endoscopic therapies, including intraluminal endoscopic surgery. Full-thickness resection, intraluminal anastomoses, and closure of perforations are all likely procedures to be seen in the very near future, and it is imperative that surgeons stay attentive to the advancements in these technologies.

19 LOWER ENDOSCOPY

Brian J. Dunkin, MD, FACS, and Rohan A. Joseph, MD

The lower endoscopy revolution began in 1967 with the development of the first flexible fiberoptic sigmoidoscope by Bergein F. Overholt.¹ Although the idea for fiberoptic examination of the colon was first conceived by Robert Turell in 1963, he failed to pursue it because of skepticism over its potential for success. The breakthroughs in flexible fiberoptic technology by Harold Hopkins and the invention of the first flexible gastroscope by Basil Hirschowitz in 1958 convinced Dr. Overholt of the possibility of endoscopic examination of the colon and enabled him to develop the device for which he is now credited. In 1970, a longer version of the Overholt sigmoidoscope was devised with four-way tip deflection that enabled navigation of the colonic flexures. Between 1970 and 1973, colonoscopy started gathering increased acceptance across the United States as more diagnostic and therapeutic procedures were demonstrated to be safely performed.¹

Definition

Lower endoscopy includes rigid and flexible sigmoidoscopy, colonoscopy, endoscopic ultrasonography (EUS), and anoscopy. This chapter focuses on the diagnostic and therapeutic maneuvers performed using a colonoscope. A separate section is included at the end to give special attention to the other modalities.

Indications

The indications for performing colonoscopy can be classified into two categories: diagnostic and therapeutic [see Table 1]. The most common diagnostic indication is for screening or surveillance of colorectal neoplasms and evaluation of colonic lesions. Investigation of gastrointestinal (GI) blood loss and unexplained abdominal pain are also frequent indications. Therapeutic indications include the removal of

polyps, treatment of bleeding, decompression, and stenting. Contraindications to colonoscopy include disease states that increase the risk of perforation, such as recent diverticulitis (within 2 to 4 weeks), suspected perforation, or gangrenous ischemic colitis.

Diagnostic and Screening Colonoscopy

Colon cancer is the third most common cause of cancer death among men and women in the United States, with approximately 50,000 deaths annually.^{2,3} Most cancers arise from adenomatous polyps less than 1 cm in size and take almost 10 years to become invasive cancer. Screening programs have resulted in a decreased incidence of colon cancer as revealed in multiple cohort studies comparing them with patients without any form of screening.^{2,3} Interestingly, no current studies have examined whether screening reduces colon cancer–related mortality. The ability of colonoscopy to thoroughly visualize the lower GI mucosa, detect lesions, and remove them while obtaining tissue for histologic diagnosis makes it an effective tool for screening and surveillance.

The risk for colon cancer increases with age. Patients who only have age as a risk factor are considered to be at “average risk” [see Table 2]. Individuals with personal and familial risk factors are considered to be at “high risk” [see Table 2]. The recommendations by the US Multi-Society Task Force for screening and surveillance in colorectal cancer (CRC)² are highlighted in Table 2.

A newer technique called virtual colonoscopy (VC) or computed tomographic (CT) colography is finding more acceptance and popularity among providers and patients alike. This technique employs CT, rapid volumetric imaging, and three-dimensional image rendering made possible by contrast differences between intraluminal air, the colonic wall, and the surrounding soft tissues. Patients have to undergo a standard bowel preparation, and images are acquired in the supine and prone positions. Prior to the examination, a soft rubber catheter attached to a bulb syringe is then inserted into the rectum and the bowel is insufflated with either room air or carbon dioxide. The patient’s subjective assessment of abdominal discomfort and fullness is a good indicator of bowel distention. Analyses of reports indicate a sensitivity and specificity of 75% and 90%, respectively, for adenomatous polyps larger than 10 mm in diameter, 66% and 63% for adenomas larger than 5 mm, and 45% and 80% for polyps smaller than 5 mm.⁴ There are currently no studies that demonstrate a decrease in CRC incidence or mortality using VC, and concerns over radiation exposure have been expressed. VC may be recommended for patients who refuse colonoscopy or have an inadequate bowel preparation but is not currently endorsed by the American Society for

Table 1 Indications for Colonoscopy

Diagnostic
Screening and surveillance of GI neoplasms

Table 2a Recommendations for Screening and Surveillance in Colorectal Cancer (Average-Risk)

Average-Risk Individual	Preferred Modality	Alternative
Begin screening at 50 yr	Colonoscopy every 10 yr	Annual fecal occult blood test (FOBT) Flexible sigmoidoscopy every 5 yr Annual FOBT and flexible sigmoidoscopy every 5 yr

Table 2b Recommendations for Screening and Surveillance in Colorectal Cancer (High-Risk)

High-Risk Individual with	Screening Strategy
FAP	Annual sigmoidoscopy beginning at 10–12 yr of age followed by colectomy when polyps develop
HNPCC	Colonoscopy beginning at 20–25 yr of age and repeated every 1–2 yr or colonoscopy performed 10 yr earlier than the first known diagnosis of cancer in the family, whichever is earlier Annual colonoscopy is recommended after 40 yr
IBD	Colonoscopy every 1–2 yr after 8–10 yr of the disease
CRC in a first-degree relative younger than 60 yr or two first-degree relatives of any age	Colonoscopy at 40 yr or performed 10 yr earlier than the affected relative, whichever is earlier If screening colonoscopy is normal, follow-up screening examinations are done every 5 yr subsequently
CRC in a first-degree relative older than 60 yr or two second-degree relatives of any age	Colonoscopy at 40 yr If screening colonoscopy is normal, follow-up screening examinations are done every 10 yr subsequently
Personal history of adenomas on previous endoscopy	1–2 tubular adenomas < 1 cm in size: perform surveillance in 5 yr 3 or more adenomas: perform surveillance in 3 yr Advanced adenomas (> 1 cm, high-grade dysplasia or villous elements): perform surveillance in 3 yr
Adenomatous polyp in a first-degree relative younger than 60 yr	Screening colonoscopy at 40 yr or performed 10 yr earlier than the affected relative, whichever is earlier If normal, screening colonoscopy is carried out every 3–5 yr subsequently
Adenomatous polyp in a first-degree relative older than 60 yr	Screening colonoscopy at 40 yr If normal, perform surveillance as for an average-risk individual
After curative surgery for colon cancer	Repeat colonoscopy at 1 and 3 yr and then at 5 yr intervals if normal
After curative surgery for rectal cancer	Repeat colonoscopy at 1 and 4 yr and then at 5 yr intervals if normal

Recommendations by the US Multi-Society Task Force. CRC = colorectal cancer; FAP = familial adenomatous polyposis; HNPCC = hereditary nonpolyposis colon cancer; IBD = inflammatory bowel disease.

Gastrointestinal Endoscopy (ASGE) as a standard screening modality.² Patients with lesions detected on VC must undergo a complete colonoscopic examination.

Bowel Preparation for Colonoscopy

A critical element to safe and accurate colonoscopy is the proper cleansing of the colon. To date, no ideal agent has been identified, and the evolution of agents for cleansing reveals a significant transformation with respect to methods used in the past. High-volume gut lavage and rectal pulsed irrigation are only of historic importance today. All patients are advised to take a clear liquid diet on the day prior to the procedure in combination with a bowel cleansing regimen. The use of diet modifications and enemas alone is insufficient to obtain optimal preparation, but they are used as adjuncts to the agents listed below. A joint consensus statement on bowel preparation prior to colonoscopy was published in 2006 by the American Society of Colon and Rectal Surgeons (ASCRS), ASGE, and Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) and is summarized in Table 3.⁵

Patients who present for the procedure without completing their bowel regimen are best managed by rescheduling the

procedure for another day. Options for those who have completed the recommended preparation but failed to achieve adequate cleansing include increasing the duration of the dietary modifications, using an alternate compound, and using adjuncts such as bisacodyl and magnesium citrate in combination with the main compound.⁵ Pregnant patients may be administered a polyethylene glycol (PEG) solution in the face of data not favoring one agent over another.⁵ In pediatric patients, clear data are lacking. A widely used preparation consists of low-volume PEG dosed at 1.25 mg/kg/day for 4 days with the addition of a clear liquid diet on the last day.

Special Considerations for Patients on Anticoagulants and Antiplatelet Agents

Patients on anticoagulant and antiplatelet/antithrombotic therapy for cardiovascular conditions present the usual challenge of balancing the risk of bleeding incurred during the procedure and the risk of thromboembolism from withdrawing these medications. Tailoring of therapeutic strategies to manage these medications must be based on the procedure and patient risk factors to optimize outcomes. The commonly used anticoagulants include warfarin, heparin, and low-molecular-weight heparin. The commonly used antiplatelet

Table 3 Agents for Bowel Preparation Prior to Colonoscopy

Agent	Commercial Name	Comments
Polyethylene glycol electrolyte lavage solution (PEG-ELS)	Colyte GoLYTELY	Passes through the colon with no net absorption or secretion Is faster and more effective than diet combined with cathartics, high-volume gut lavage, or mannitol (grade 1A) Is safer than osmotic laxatives/sodium phosphate in patients with fluid and electrolyte disturbances and hence is the preferred agent for patients with cardiac, renal, or liver disease (grade 1A) Is the proven and preferred method for cleansing in infants and children In adults, it is administered as 240 cc every 10 min until rectal output is clear or 4 L is consumed
Sulfate-free ELS	NuLYTELY TriLyte	Safety, effectiveness, and tolerance are comparable to those of PEG-ELS An alternative to PEG-ELS when a PEG-based solution needs to be used (grade 2B)
Low-volume PEG and delayed-release bisacodyl tablets	HalfLyte MiraLAX	Is better tolerated by patients because of the lower volume of fluid consumed and reduces cramping and bloating associated with consumption of 4 L of solution Combining it with bisacodyl improves the efficacy of bowel preparation (grade 1A)
Aqueous sodium phosphate	Fleet	Hyperosmotic bowel preparation that draws plasma water into the colon to induce bowel preparation Can cause fluid shifts and electrolyte derangements such as hyponatremia, hypokalemia, hypocalcemia, and hyperphosphatemia Can also induce phosphate neuropathy and nephrocalcinosis in renal patients In light of the possible fluid and electrolyte derangements, it must be used with caution in pediatric cases, geriatric populations, and patients with cardiac, renal, and hepatic insufficiency Induces mucosal ulcerations and hence must be avoided in patients with ulcerative colitis and Crohn disease Is dosed in 45 cc volumes every 12 h, with the last dose taken the morning of the procedure (grade 2B) Produces cleaning comparable to PEG-ELS (grade 1A)
Enemas	Tap water Soap suds Fleet—bisacodyl Fleet—mineral oil	Does not increase quality of preparation Used today for patients with a poor quality of preparation and those in whom the distal colonic segment is dysfunctional
Bisacodyl and magnesium citrate		Bisacodyl increases colonic motility, whereas magnesium citrate is a hyperosmotic laxative Adjuncts used in combination with PEG to reduce volume of preparation required for cleansing Does not improve quality of the preparation

agents include aspirin, clopidogrel, ticlopidine, dipyridamole, and glycoprotein inhibitors. Screening procedures and the use of “cold” biopsy techniques are considered to be at low risk for bleeding. This risk increases to 1 to 2.5% with snare polypectomies and to approximately 6% with the use of cautery devices and laser ablation. As the population ages, we find more of our patients on anticoagulant and antiplatelet medications. This has prompted the ASGE to publish guidelines for managing anticoagulant and antiplatelet medications based on the patient’s risk for developing a thrombotic complication.^{6–8} Given that the nature of the procedure to be undertaken is not known a priori, patients may require cessation of their medications for varying lengths of time. These guidelines and treatment strategies are summarized below in Table 4.

Aspirin has been shown to increase mucosal bleeding times, but the significance of this has not been demonstrated clinically. No randomized trials currently exist, and several case

control and retrospective analyses have not demonstrated an adverse outcome to continuing aspirin during a procedure. Therefore, the current recommendation is to continue aspirin in the absence of a preexisting bleeding disorder. Those patients taking a combination of clopidogrel and aspirin may be at increased risk for bleeding, and in these circumstances, withholding the clopidogrel while continuing the aspirin may reduce this risk. This increased risk for bleeding, however, is not seen in patients taking the antiplatelet agent dipyridamole either as monotherapy or in combination with aspirin; however, the safety of this combination has not been evaluated in high-risk procedures.^{6–8}

An important consideration must be given to those patients who have drug-eluting stents placed for coronary artery disease. The current guidelines advocate continuing dual-antiplatelet therapy (e.g., aspirin and clopidogrel) for a minimum of 1 month after placement of a bare metal stent and 1 year after placement of a drug-eluting stent to allow

Table 4 Guidelines and Strategies for Managing Anticoagulant and Antiplatelet Medication for Lower Endoscopy

Patient	High-Risk Procedure*	
	Warfarin	Antiplatelet Agents
High risk 1. Mechanical valve [†] in the mitral or aortic position 2. Those with atrial fibrillation and underlying cardiac or valvular disease	Stop warfarin 3–5 days prior. Use heparin (UFH/LMWH) as a bridge to maintain therapeutic anticoagulation. Stop heparin 4–8 hr before the procedure Resume heparin 2–6 hr after the procedure and gradually reinstitute warfarin until INR is in therapeutic range	Consider discontinuation at least 7–10 days before the procedure Reinstitution should be individualized
Low risk 1. Mechanical valves [†] in other sites 2. Atrial fibrillation without underlying cardiac or valvular disease 3. DVT	Stop warfarin 3–5 days prior and resume within 24 hr postprocedure	Individualize need for therapy based on risk and work with patient's cardiologist
Patient	Low-Risk Procedure [‡]	
	Warfarin	Antiplatelet Agents
High risk 1. Mechanical valve [†] in the mitral or aortic position 2. Those with atrial fibrillation and underlying cardiac or valvular disease	Continue warfarin. Delay procedure while INR is supratherapeutic.	No change in therapy as long as there is no previous issue of bleeding or Individualize therapy based on risk and work with patient's cardiologist
Low risk 1. Those with mechanical valves [†] in other sites 2. Those with atrial fibrillation without underlying cardiac or valvular disease 3. Those with DVT	Continue warfarin. Delay procedure while INR is supratherapeutic.	No change in treatment regimen required or Individualize therapy based on risk and work with patient's cardiologist

DVT = deep vein thrombosis; INR = international normalized ratio; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin.

*High-risk procedures: polypectomy, pneumatic or bougie dilation, laser ablation, and coagulation.

[†]Patients with caged-ball or disk valves have a higher risk than those with bileaflet, tilting, or bioprosthetic valves.

[‡]Low-risk procedures: screening/surveillance colonoscopy ± biopsy.

reendothelialization and preventing stent thrombosis from premature drug cessation. Elective and semielective procedures should be delayed during this time. At the time of endoscopy, the patient is usually maintained on one agent, usually aspirin because more data are currently available on the safety of aspirin during procedures compared with clopidogrel.

Endocarditis Prophylaxis

It was originally believed that colonoscopy increased the risk of endocarditis as a result of the resulting bacteremia that occurred during the procedure. Contemporary studies cite the risk of bacteremia during colonoscopy to be between 0 and 25%, with a mean frequency of 4.4%.⁹ Updated guidelines regarding the indications for antibiotics in patients with prosthetic devices have been published and are based on the American Heart Association (AHA) guidelines. Patients with a history of bacterial endocarditis, vascular grafts placed within 1 year of the procedure, prosthetic cardiac valves including bioprosthetic and homograft valves, and surgically created pulmonary or systemic conduits are considered to be at higher risk for bacterial seeding. These patients may be given antibiotics at the discretion of the endoscopist while undergoing a colonoscopy with or without biopsy or polypectomy. However, antibiotics are recommended should these

patients require a dilation of a stricture during colonoscopy.⁹ All other subgroups of patients who have prosthetic devices such as joint prostheses, penile prostheses, pacemakers, and implanted defibrillators are considered to be at low risk for infection, and antibiotic prophylaxis is discouraged.⁹ Prophylactic antibiotics should be administered as follows: a single dose of 2 g of ampicillin IV and gentamicin (1.5 mg/kg to a maximum of 80 mg) administered 30 minutes prior to the procedure. In the case of a penicillin allergy, vancomycin 1 g IV can be substituted and should be given together with gentamicin.

General Technique

Colonoscopy begins with the proper selection and preparation of the patient. Informed consent should be obtained and a complete history and physical examination done with particular emphasis on the cardiopulmonary system. It is also important to be aware of previous abdominal surgery such as hysterectomy or colon resection as these can alter the anatomy of the colon.

The setup for colonoscopy is depicted in Figure 1a. The procedure is performed with the patient in the left lateral position and with intravenous sedation to increase patient comfort. An adult or pediatric colonoscope may be used. The adult colonoscope has a slightly increased diameter in

a

b

Figure 1 (a) Room setup and patient positioning for colonoscopy. (b) Technique for insertion of a colonoscope.

comparison with the pediatric scope but provides a larger instrument channel and increased shaft stiffness, which may reduce looping. The pediatric scope's smaller diameter may be more comfortable for the patient and allows easier traversal through narrow or angulated areas. It may also improve the endoscopist's ability to traverse the ileocecal valve. The procedure begins with a digital rectal examination to relax the sphincter muscles and screen for anal canal lesions. The well-lubricated colonoscope is then inserted into the anal canal by holding it approximately an inch from the tip and placing it against the patient's perineal body while sliding back and applying pressure toward the anus [see Figure 1b]. This maneuver causes the tip of the endoscope to gradually dilate the anus and reduces mechanical trauma to the anal canal during insertion. As the instrument is passed into the rectum, small amounts of air are insufflated and debris is washed from the lens. Traversing the colon expeditiously requires the endoscopist to use the minimum amount of insufflation to maintain visualization while managing the deflection wheels with the left hand and the endoscope shaft with the right.

Overinsufflation during entry stretches and elongates the colonic flexures and makes traversal more difficult and uncomfortable. The rectal mucosa is identified by its prominent reticular vascular markings and the semilunar valves of Houston that appear in an alternating fashion [see Figure 2a]. As the endoscope is advanced into the sigmoid colon, a combination of tip deflection and shaft torque is used to negotiate this tortuous part of the colon. The long, floppy, and mobile character of the sigmoid colon makes it a common site for loop formation. Further, in patients with previous pelvic surgery, dense peritoneal adhesions to the sigmoid can increase the difficulty of traversal. The endoscope should not be advanced blindly if possible or with excessive force as bowing of the shaft can risk colonic wall perforation. Failure of the tip of the scope to advance while more shaft is introduced transanally is called paradoxical motion and suggests loop formation [see Figure 2b]. Such loop formation may be reduced by pulling back on the shaft of the endoscope so as to straighten it. A jiggling motion while pulling back may cause

Figure 2 (a) Endoluminal view of rectum with semilunar valves. (b) Loop formation during scope advancement. (c) Direction of lumen indicated by mucosal concavity. (d) Endoluminal view of descending colon. (e) Endoluminal view of transverse colon. (f) Endoluminal view of cecum.

the colon to telescope over the instrument and further helps with loop reduction. The scope is then traversed through the sigmoid colon with the direction of the lumen identified by the concavity of the mucosal folds [see Figure 2c].

The descending colon is identified by the concentric circular pattern of the mucosa, and traversal to the splenic flexure is usually straightforward [see Figure 2d]. The splenic flexure is identified by pooling of fluid and a sharp angulation into the transverse colon. Occasionally, the bluish hue of the spleen can be seen through the colon wall. The transverse colon is identified by the triangular appearance of the lumen formed from omental traction on the tenia [see Figure 2e]. The transverse colon is relatively easy to maneuver through, and the appearance of a bluish hue over the mucosa suggests entry into the hepatic flexure. Commonly, entry into the ascending colon must be accompanied with scope withdrawal and left-hand torque to straighten all flexures and allow traversal into the cecum. Moving the patient into a supine position and applying external pressure to the sigmoid colon are adjuncts that can aid cecal intubation. The cecum is identified by the appearance of the convergence of the colonic tenia at the appendiceal orifice, the appearance of which is often called the “Mercedes” sign. Further, the central appendicular orifice and the liplike mucosal folds of the ileocecal valve are seen [see Figure 2f]. The valve can be intubated to gain access to the lumen by deflecting toward it while pulling back on the endoscope and insufflating gently. Not all endoscopists intubate the ileum routinely, but it should certainly be done when there are specific indications such as possible inflammatory bowel disease or unexplained iron deficiency anemia.

After successful cecal intubation, the colonic mucosa is carefully inspected during withdrawal of the endoscope. Care is taken to flatten the mucosa and look behind each fold and flexure. Obscuring fluid should be aspirated or the patient position changed to move debris out of the way. Evidence from a study by Barclay and colleagues suggests that scope withdrawals done in less than 8 minutes have an increased propensity to miss subtle adenomas that may harbor neoplasia.¹⁰ The procedure ends with retroflexion in the rectum to inspect the anal canal and area of the dentate line, followed by evacuation of insufflation.

Diagnostic and Therapeutic Techniques during Colonoscopy

During inspection of the colonic mucosa, pathology is often identified that requires sampling, marking, or a therapeutic maneuver such as excision. What follows is a description of techniques available to the endoscopist.

BIOPSY

The most common technique of tissue sampling during colonoscopy is to perform a pinch biopsy. This entails delivering a biopsy forceps to the desired target and taking a sample without applying any electrocautery. Many biopsy forceps have a spike at their base that holds the first “bite” in place and allows obtaining a second “bite” before withdrawing the device [see Figure 3a].

POLYPECTOMY

Polypectomy is by far the most common therapeutic procedure performed during colonoscopy. Several techniques have been developed to improve the safety and efficacy of the procedure, and polyps are excised using either a snare or a “hot” biopsy forceps.

Figure 3 (a) Pinch biopsy forceps. (b) Hot biopsy forceps.

Hot Biopsy

For those polyps less than 3 mm in size, excision with a “hot” biopsy forceps [see Figure 3b] can be sufficient. A hot biopsy forceps differs from that used during regular biopsy in that it delivers monopolar electromechanical energy to the jaws to enable tissue destruction. During hot biopsy, the lesion is grasped with the forceps and distracted away from the underlying submucosa. Brief applications of electrocautery are then applied until a white zone of coagulum at the base of the polyp is seen. In theory, this technique allows sampling of the lesion to determine its pathology while destroying any remaining tissue to minimize recurrence or continued growth. Although still practiced, there is controversy about the efficacy of the hot biopsy technique. Gilbert and colleagues reported that hot biopsy techniques failed to reduce the incidence of CRC and were not associated with complete obliteration of the lesion.¹¹ Further, the procedure risks deep tissue injury, with the consequent complications of bleeding, perforation, and postpolypectomy syndrome [see Postpolypectomy Complications, *below*]. In 1992, Tappero and colleagues described a “cold” biopsy technique as an alternative to hot biopsy in 210 consecutive patients in whom 288 polyps less than 5 mm were excised without diathermy.¹²

They reported this alternative to be safe and comparable to the conventional hot biopsy technique in adequacy of tissue acquisition for histopathology.

A prospective study by Mönkemüller and colleagues in 2004 asked pathologists blinded to the fashion in which the specimen was acquired (hot versus cold biopsy) to evaluate the specimen quality and found a significant rate of architectural distortion and tissue fragmentation in samples acquired by hot biopsy.¹³

Sessile or pedunculated lesions between 3 mm and 2 cm are snare excised. For pedunculated polyps, it must be borne in mind that the stalk represents an extension of normal mucosa and does not need to be excised completely. The snare is advanced beyond the polyp such that the sheath of the snare rests over the lesion. Gentle drawing back of the snare brings it into position over and around the polyp. Once the snare is tightened, brief bursts of cautery are applied while distracting the lesion away from the submucosa so as to prevent transmural thermal injury [see Figure 4a]. The excised polyp must then be retrieved for pathologic examination either by suctioning it through the colonoscope and into a specimen trap (small polyps) or retrieving it directly by attaching it to the tip of the scope (by suction, snare, or basket) and removing it.

Figure 4 (a) Snare polypectomy of a pedunculated polyp. (b) Endoscopic mucosal resection (EMR) of a sessile polyp using the lift and cut technique. (c) EMR of a sessile polyp using a suction cap.

Sessile polyps greater than 2 cm may not be amenable to simple snare excision without risking injury to the colonic wall. This risk can be reduced by resecting the polyp in a piecemeal fashion using endoscopic mucosal resection (EMR). EMR was first described by Tada in 1984 for dealing with giant sessile lesions in the stomach.¹⁴ It has been safely and effectively applied to similar lesions in the colon. EMR begins with a simple saline lift of the submucosa followed by a piecemeal resection of the lesion using a polypectomy snare [see Figure 4b].

Alternately, EMR can be performed by mounting a transparent suction cap (EMR-C) to the distal end of the endoscope. After a saline lift is performed, a portion of the lesion is aspirated into this cap, and then an open snare is passed around the base of the lesion. These steps are repeated several times until the entire lesion is excised in a piecemeal fashion [see Figure 4c]. EMR affords a greater amount of tissue for resection, thereby optimizing histologic evaluation. Furthermore, lesions located tangentially and those within interhastral folds are better approached with this technique. EMR-C is a painstaking yet rewarding procedure, with an overall complication rate of 10%, which is comparable to standard snare polypectomy techniques.^{15,16}

The treatment strategies for pedunculated polyps excised at polypectomy are best governed by the Haggitt classification.¹⁷ This stratification of treatment depending on the degree of invasiveness of the lesion has demonstrated prognostic importance [see Figure 5]. This classification is depicted in Table 5.

Lesions from levels 0 to 2 are treated with polypectomy alone. For a level 3 lesion, polypectomy is adequate as long as a 2 mm negative margin is present, the cancer is not poorly differentiated, and no lymphatic or vascular invasion is present. Level 4 lesions are treated with segmental colectomy because of the higher risk of lymphatic invasion.

It is usually a wise strategy to tattoo lesions that appear suspicious for malignancy. This is often done with a permanent carbon-based dye injected into the submucosa circumferentially in an area proximal to the lesion. These markings are usually visible from the outside of the lumen during surgery. This is an invaluable tool that enables the surgeon to locate the lesion and acquire appropriate operative margins.

Novel approaches to polypectomy using laparoscopic assistance have been described for those polyps that are hard to access endoscopically and for giant sessile polyps. A review of cases done by Franklin and colleagues described the advantages of laparoscopy-assisted endoscopic polypectomy to include the ability to laparoscopically mobilize the colon so as to enable better access to polyps along flexures, the ability to laparoscopically repair a transmural injury should that occur during excision of giant sessile polyps, or the opportunity to perform a colectomy during the same procedure should the frozen section be positive for an invasive carcinoma.¹⁸

Postpolypectomy Complications

The Munich Polypectomy Study (MUPS), a large, multicenter, prospective trial evaluating risks and complications in 4,000 snare polypectomies, found that the risk of complication increases when polyps are located in the right colon and greater than 1 cm in diameter or located in the left colon and greater than 2 cm in diameter or if multiple polyps are resected.¹⁶ The overall complication rate in this study

Figure 5 Haggitt classification of tissue invasion in a pedunculated polyp.

was 9.7%, with a bleeding risk of 8.6% and a perforation risk of 1.1%.

Postpolypectomy syndrome occurs in 2 to 3% of patients undergoing polypectomy and is the result of a transmural thermal injury with subsequent serosal inflammation. Most patients present with abdominal pain and fever. Workup includes an abdominal and pelvic CT scan to look for evidence of colonic perforation. If there is none, the patient is managed by avoiding oral intake and the administration of

parenteral antibiotics along with serial abdominal examinations. Most patients can be managed nonoperatively in this fashion. Those patients who develop signs of peritonitis require surgical exploration and primary repair of the injury. This is usually sufficient because the colon has been recently cleansed and contamination is usually minimal.

HEMOSTASIS

Lower endoscopy as a diagnostic and therapeutic tool for management of colonic bleeding is indicated in patients with spontaneous cessation as well as those with ongoing hemorrhage. Although, traditionally, radionuclide scans and angiography in concert with surgery were the first-line treatments, there is now greater advocacy and acceptance of the use of colonoscopy to manage these cases at the outset. Of course, good clinical judgment should be exerted to identify those patients with massive hemorrhage and hemodynamic instability who would benefit from angiography and/or an early trip to the operating room.

Historically, the role of urgent colonoscopy (defined as a procedure within 12 to 48 hours of admission) for lower GI bleeding has been questioned. This arose due to concerns of inadequate visualization and the fact that most bleeding stops spontaneously. However, several studies have demonstrated that colonoscopy under urgent conditions is safe and feasible after prior rapid cleansing, with a diagnostic yield of between 74 and 90%. This is higher than both radionuclide scans

Table 5 Haggitt Classification of Tumor Invasiveness in an Adenomatous Polyp	
Level	Histology Findings
0	Carcinoma in situ or intramucosal carcinoma. Not invasive.
1	Carcinoma invading through muscularis mucosa into submucosa but limited to the head of the polyp
2	Carcinoma invading the level of the neck of the adenoma
3	Carcinoma invading any part of the stalk
4	Carcinoma invading into the submucosa of the bowel wall below the stalk of the polyp but above the muscularis propria

and angiography, although no studies have compared these procedures head to head in a randomized fashion.¹⁹

The bowel preparation for the procedure is undertaken simultaneously with the resuscitation efforts and consists of 1 L of PEG administered orally or via a nasogastric tube every 30 to 45 minutes until the stool effluent is relatively clear. The administration of metaclopramide improves gastric emptying and may be a useful adjunct.

The tools for acquiring hemostasis include the following:

- *Vasoconstricting agents.* The most common method of gaining initial hemostasis is by injection of epinephrine, typically in a 1:10,000 concentration. It is injected into the submucosal layer to gain temporary hemostasis and as an adjunct to thermal therapy. Common side effects are transient tachycardia and hypertension. When bleeding obscures the field of view, irrigation with blind injection around an area of clot is considered safe.¹⁹
- *Thermal devices.* Applying thermal energy to a bleeding lesion either alone or in combination with injection therapy is another common strategy for gaining endoscopic hemostasis. Thorough knowledge of the principles of electrosurgery is critical for this technique. A comprehensive review of this topic is beyond the scope of this chapter, but a basic understanding of the types of electrosurgical energy is reviewed. Cauterizing a lesion with electromechanical energy (electrocautery) is simply the act of applying an alternating electrical current via a device to the desired tissue. Patients are not “shocked” by this energy the way they would be if they came in contact with a common wall outlet because it is delivered at a very high frequency in the radiowave spectrum (radiofrequency). All electrocautery requires a complete circuit to be delivered to the desired tissue. There are essentially two ways to complete this circuit. Monopolar electrocautery completes the circuit by the electrical current passing through the patient. Bipolar electrocautery passes through the affected tissue only. Monopolar electrocautery can penetrate deeply into tissues and is effective for hemostasis but risks deep thermal injury and possible perforation in thin-walled structures. Bipolar energy does not penetrate as deeply but may be less effective in gaining hemostasis. Thorough knowledge of these principles, along with proper energy settings on the generator used for electrocautery, is critical for the safe application of this technology. Argon plasma coagulation (APC) is a special version of monopolar electrocautery that requires additional understanding. Argon gas, when “electrified,” is converted to plasma, which conducts monopolar electricity. This principle is very useful in situations where it is desirable to apply electrocautery to large surface areas without risking deep tissue penetration. An additional benefit of the APC probes is that they enable the application of electrocautery without actually touching the tissue, which prevents the buildup of debris on the probe tip and allows for the expeditious “painting” of large surface areas. Understanding the unique energy settings and argon gas flow rates for operating an APC probe is essential. Being mindful to constantly aspirate the argon gas from the GI tract is also important. Another method of applying thermal energy to tissue in the GI tract is through use of a Teflon-tipped probe that is heated to a

desired level. This “heater probe” does not apply electrocautery to the tissue but simply cauterizes it by generating heat at its tip. Understanding the energy settings available on this probe and the conformity of its tip is important for its proper use.

- *Endoscopic clips.* Endoscopically placed clips [see Figure 6] are an excellent technology used to manage bleeding from discrete sources, such as the mouth of a diverticulum or postpolypectomy bleeding site, and can be applied multiple times. These clips are also excellent for controlling bleeding from a fresh anastomosis when injection and thermal application are undesirable.

DECOMPRESSION

Colonoscopic decompression has been performed in unprepared bowel for sigmoid volvulus and colonic pseudo-obstruction (Ogilvie syndrome). This nonsurgical approach may serve as an invaluable bridge to surgery in those critically ill and elderly patients who may not be able to withstand a surgical operation.

For sigmoid volvulus, the endoscope is advanced beyond the point of torsion gently, without excessive force and while keeping the lumen in sight at all times. Once the bowel is detorsed, contents from the proximal bowel are suction evacuated to decompress it [see Figure 7, a, b]. The decompressed state of the colon is maintained by placing a long rubber catheter in the proximal colon using endoscopic guidance [see Figure 7c].

STENTING

The first reported use of colonic stenting for treatment of large bowel obstruction was by Spinelli and colleagues in 1992.²⁰ Several subsequent studies have further validated its efficacy, and indications for their use are as follows:

- *Preoperative decompression.* In patients who present with acute obstruction from a primary colorectal malignancy, use of a stent to relieve the obstruction decreases the likelihood of requiring emergent surgery and the need for a colostomy. A one-stage en bloc resection of the cancer can be performed subsequently once the obstruction is relieved and the patient’s condition has optimized. Several prospective and retrospective studies have confirmed this. A large study by Dauphine and colleagues examining the role of stents used for preoperative decompression from 1990 to 2000 revealed that stenting was a successful bridge to surgery in 85% of cases and 95% of patients benefitted from a single-stage procedure.²¹ However, data from prospective studies randomizing patients to a stenting versus emergent surgery arm are lacking.
- *Palliation of obstruction.* In those patients with primary or recurrent CRC who are not operative candidates, endoscopic stents can be used as a means of palliation. In the same study by Dauphine and colleagues, stenting averted a colostomy in 90% of the patients.²¹
- *Palliation of malignant fistulas.* Sealing a colovesical or colovaginal fistula for palliation is another indication for stenting, although firm evidence to support this treatment modality is lacking.

Stenting is contraindicated in the presence of a perforation, and this must be definitely excluded prior to the procedure.

Figure 6 (a) Endoscopic clips. (b) Endoscopic clip application.

Similarly, benign strictures are a relative contraindication, although stents have been deployed in these circumstances.

Colonic stents are referred to as self-expanding metal stents and are made of woven, knitted, or laser-cut metal mesh cylinders that exert radially expansive forces when deployed, which helps keep them in position [see Figure 8a]. Some stents designed for the esophagus or bile duct are covered with a plastic membrane to prevent tumor ingrowth, but colonic stents are uncovered to allow better fixation and prevent migration. These stents usually foreshorten after deployment, which is an important consideration while choosing the length of stent to be deployed. A variety of stents are available, and their salient features are summarized in Table 6.

These stents are passed over a guide wire and are deployed with or without through-the-scope (TTS) assistance, usually with fluoroscopic guidance. The stents are mounted on delivery systems that differ with regard to the design of their handles and the release of the constricting mechanism. Most delivery systems release the stent at the distal end first.

Prior to stenting a patient with an obstruction, it is important to rule out any other proximal source of obstruction and to characterize the degree and length of the obstruction. An enema may be given prior to the procedure, although most patients with a high-grade obstruction have already evacuated stool below the lesion.

For non-TTS stent placement, a guide wire is passed through the endoscope, across the lesion, and as proximal as possible. The endoscope is withdrawn, and the nondeployed stent is advanced over its delivery system and across the stricture. The endoscope is reinserted to verify optimal positioning of the distal end of the stent and then deployed under direct vision. Positioning of the waist of the stent across the middle of the obstruction indicates optimal placement.

For TTS stent placement, a guide wire is passed across the obstruction and up to 20 cm proximally. The nondeployed stent is placed under direct endoscopic guidance and deployed after confirming optimal positioning [see Figure 8, b, c, and d].

Reported complications from stenting include perforation, migration, and bleeding. Perforation is the most devastating complication and negates the reason for the procedure in the first place, which was to avoid a colostomy and facilitate a one-stage resection. The risk of intraprocedural perforation may be reduced by limiting insufflation.²¹ Stent migration can be asymptomatic or present with rectal pain, bleeding, tenesmus, or fecal incontinence if the stent migrates distally. Typically, as long as the stent remains 2 cm above the anal canal, it does not produce symptoms and can be easily removed. Obstruction of the stent by tumor ingrowth is usually managed by placement of new stents across the old one. The study by Dauphine and colleagues alluded to earlier in

Figure 7 Colonoscopic decompression.

this chapter examined all cases of stent placement from 1990 to 2000 and reported a mortality of 1%, a perforation rate of 0 to 7%, a migration rate of 3 to 22%, bleeding in 0 to 5%, and a reobstruction rate of 0 to 15%.²¹

BALLOON DILATION

The endoscopic management of anastomotic and other benign strictures by balloon dilation provides a relatively non-invasive method to a problem that was long managed surgically. Similar to their role in upper endoscopy, endoscopic balloon dilation lends itself well to the management of benign colonic strictures. The procedure is optimally performed under fluoroscopic guidance, and a gentle bowel preparation to cleanse the colon distal to the stricture is recommended. The deflated balloon is passed through the working channel of the endoscope and positioned across the stricture. Under endoscopic and fluoroscopic guidance, the balloon is inflated to its full diameter and left in position for 1 to 2 minutes. It is then deflated and withdrawn, and the area of dilation is endoscopically inspected for evidence of bleeding or perforation. The procedure may be repeated at 2- to 4-week intervals as necessary, and patients should be advised that multiple sessions are frequently required to obtain maximum therapeutic benefit. Although reports indicate a median number of approximately 2.6 dilations to maintain long-term patency, a retrospective review by Araujo and Costa on patients after low anterior resection did not find a relation between the number of dilation sessions and recurrence.²²

Sigmoidoscopy

The advent of the sigmoidoscope was the first breakthrough in lower endoscopy. Although less in favor and less frequently performed today, it is still a valuable diagnostic and therapeutic tool for conditions of the lower colon and rectum. Indications for its use today include evaluation of a change in bowel habits, bleeding, and lower abdominal pain and as a screening tool for CRC. It is usually performed in the doctor's office after an enema and requires no sedation. Although no prospective studies exist that demonstrate a reduction in CRC mortality from sigmoidoscopy, case control studies have suggested a decrease in the incidence of CRC in the examined areas, with benefits lasting up to 10 years.²³ However, the risk of cancer in the colon beyond the reach of the sigmoidoscope is not reduced, and multiple studies have confirmed that advanced proximal adenomas may exist even in the absence of more distal lesions.^{6,23,24} Flexible sigmoidoscopy is currently recommended as an alternative screening tool to colonoscopy every 5 years.

Certain findings on sigmoidoscopy predict a higher risk for proximal advanced neoplasia and warrant a more complete colonoscopic examination. These include villous histology of the distal adenoma, adenomas greater than 1 cm, and multiple adenomas. Adenomas less than 1 cm may be excised using a cold snare technique and can be histologically distinguished as hyperplastic or inflammatory in nature. Electromechanical energy should not be used in the unprepared bowel to avoid explosion.

Figure 8 (a) Self-expanding uncovered metal stents. (b, c, d) Self-expanding uncovered metal stent being deployed in a patient with a malignant obstruction. A guide wire is passed through the obstruction. The collapsed stent is passed over the guide wire and across the obstruction. Once optimal position of the stent is confirmed, it is deployed. Luminal caliber is restored once the stent is in position.

Anoscopy

Anoscopy employs a lubricated speculum [see *Figure 9*] to visually inspect and examine the anal canal. It is performed in the doctor's office or emergency department and may be used to diagnose hemorrhoids, anal fissures, fistulas, abscesses, tumors, and bleeding from the anal canal. Maneuvers such as banding of prolapsed hemorrhoids, biopsies of tumors, fulguration of warts, drainage of small superficial abscesses,

and application of silver nitrate to bleeding points may also be safely carried out using anoscopy. Anoscopy requires a minimal preparation such as an enema and produces minimal discomfort. It should be performed carefully after recent anal or rectal surgery.

Figure 9 Anoscope.

Table 6 Colonoscopic Stents and Features	
Material	Comments
Nitinol	A nickel, titanium alloy that is flexible enough to allow stenting across sharply angulated areas at the cost of reduced radially expansive forces Decreased incidence of migration by creating wider flare at its proximal end Foreshortens by 23% when deployed
Elgiloy	A cobalt, chromium, and nickel alloy that is corrosion resistant and exerts high radial forces when deployed Allows through-the-scope deployment Foreshortens by 39–49% when deployed
Stainless steel	Does not foreshorten when deployed

Endoscopic Ultrasonography

The scope of EUS is more limited in lower endoscopy when compared with its application during esophagogastroduodenoscopy (EGD) and endoscopic retrograde cholangiopancreatography (ERCP). EUS uses rigid endorectal probes [see Figure 10a], flexible radial and longitudinal ultrasonographic echoendoscopes, and catheter miniprobe that can be passed through the working channel of the endoscope. A schematic of the endoluminal anatomy as visualized during EUS is depicted in Figure 10b.

Endorectal ultrasonography is an invaluable tool for preoperative staging in rectal cancer [see Figure 10, c and d] and helps stratify those patients who would benefit from local excision versus radical resection as well as the need for neoadjuvant chemoradiation. It is also used for surveillance after surgery to detect local recurrence of tumor.

EUS is also used to guide the management of complicated fistulas [see Figure 10e] in patients with perianorectal inflammatory bowel disease. Patients with complex perineal fistulas from Crohn disease usually undergo a protracted course of medical and surgical therapy, which is dictated by the clinical discretion of the surgeon. With EUS, superior anatomic delineation of the fistula in relation to the sphincter and identification of occult internal openings and abscesses can guide the surgeon in deciding the optimal course of treatment for these complex problems. A retrospective study by Schwartz and colleagues in 21 patients with complex perineal fistulas treated by a combination of medical and surgical therapy guided by serial EUS revealed that 86% of patients had initial cessation of drainage, whereas 76% had long-term cessation.²⁵ Furthermore, a small, randomized, prospective study by the same group demonstrated that when EUS was used to guide treatment, 80% of patients responded completely compared with 20% of patients in the control arm, whose management strategy was solely at the clinical discretion of their provider.²⁶ At this time, the ASCRS recommends the use of EUS as a beneficial adjunct in the management of these patients.²⁷ The use of EUS requires special training and knowledge of the principles of ultrasonography to avoid misinterpretation.²⁸

Lower Endoscopy Training and Innovations on the Horizon

There is currently a deficiency of consistent and curriculum-driven endoscopy training for general surgeons. This has made it difficult for surgeons in training to gain adequate experience in colonoscopy so that they feel confident in performing the procedure. In fact, rural surgeons perform flexible endoscopy more frequently than any other procedure but report a lack of confidence in doing so at the beginning of their practice as a result of either inadequate exposure to the endoscopic platform or lapsed time periods between their rotation as a junior resident and use of the endoscope as a senior resident.²⁹

The American Board of Surgery acknowledges the importance of learning colonoscopy during residency and, as part of this acknowledgment, has recently increased the required number of cases for general surgery board certification. Although it is logical to believe that doing more procedures

results in better performance, there is considerable debate about what numbers to use and if numbers by themselves are an adequate indicator of competency. Some believe that the real underlying problem in endoscopy training is the lack of a validated assessment tool for measuring procedural competence. Recently, Vassillou and colleagues reported on a score card to measure endoscopic proficiency. This Global Assessment of Gastrointestinal Endoscopic Skills (GAGES) provides the first validated objective measure of specific parameters required for proficiency in flexible GI endoscopy. Preliminary testing using this score card indicates that it is a consistent, reliable, and valid measure of endoscopic skill.³⁰ Such a score card may eventually replace numbers as a measure of proficiency in endoscopy.

Recognizing the challenges in learning flexible GI endoscopy, the SAGES has worked to develop a validated training and assessment program for GI endoscopy called the Fundamentals of Endoscopic Surgery (FES). This program provides Web-based didactic material on the essentials of flexible GI endoscopy, as well as a validated written examination of knowledge and a hands-on test of skill. FES may become the first “off-the-shelf” validated training and assessment tool for GI endoscopy, and it is hoped that this program will become an integral part of both surgery residency and GI fellowship training.

Over the past decade, the ultimate therapeutic endoscopic procedure has been pioneered, called natural orifice transluminal endoscopic surgery (NOTES). This type of surgery uses a flexible endoscopic platform passed into a natural orifice and across the wall of the GI tract to gain access to the peritoneal cavity. With this approach, all manner of abdominal surgery have been accomplished in animate and cadaver models, and clinical trials are currently under way for NOTES appendectomy and cholecystectomy. The transcolonic route has been described for peritoneoscopy and staging of cancer, drainage of pelvic abscesses, and urologic and gynecologic procedures. Current experiments in NOTES procedures have described using a combination of transgastric, transvaginal, and transcolonic access for full-thickness polyp resection, colostomy, and ileostomy creation, as well as right and left colon resection.³¹ These achievements, although exciting, have been limited by inadequacy of instrumentation for retraction, hemostasis and suturing, ergonomic challenges, and the inadequacy of the flexible GI endoscopic platform to perform complex surgical procedures. Lack of definitive closure devices for the colotomy also leaves many surgeons wary of pursuing these new techniques, although novel devices for endoscopic suturing are quickly becoming available, as recently reviewed in an article by Swain.³² Some of these devices have been used in small clinical trials with success.

Most reports of NOTES procedures are in animal and cadaver models, with few human case reports and even fewer case series. However, some surgeons have used the advent of NOTES to reexamine their practice and try to develop less invasive laparoscopic procedures. One example is the development of a “hybrid” NOTES approach to colon resection, where the dissection and anastomosis are performed laparoscopically, but specimen extraction is done either transanally or transvaginally.³³ Transanal endoscopic microsurgery, a procedure that uses special laparoscopic instrumentation introduced via the anus and into the rectum for transluminal

Figure 10 (a) Rigid endorectal probes for endoscopic ultrasonography (EUS). (b) Schematic of the endoluminal anatomy visualized on EUS. (c) T3 cancer invading the pericolic fat. Arrows indicate lateral limits of tumor extension. (d) Presence of lymph node enlargement in a patient with rectal cancer. The arrow indicates a 1 cm lymph node. (e) Transsphincteric fistula as visualized on EUS. The larger, thicker arrow indicates the sphincter complex. The two smaller arrows indicate the site of the fistulous opening.

full-thickness excision of rectal cancer and suture repair of the resultant defect, has been studied as a portal for NOTES surgery on the colon. In a preclinical study on porcine and cadaver specimens, Denk and colleagues demonstrated the feasibility of this platform for colonic excision and extraction using the transrectal route.³⁴ Technical challenges remain, however. Innovative redesign of instrumentation and the endoscope is currently under way to overcome these ergonomic obstacles and advance its acceptance in the surgical community.

Summary

Whether surgeons perform colonoscopy as part of their practice or work in collaboration with a gastroenterologist to provide the service, it is critical to have a thorough understanding of the technique, the indications and contraindications for its use, and potential complications. Such knowledge will allow surgeons to better use the procedure to the maximum benefit of their patients.

20 PROCEDURES FOR BENIGN AND MALIGNANT GASTRIC AND DUODENAL DISEASE

Thomas E. Clancy, MD, FACS, and Stanley W. Ashley, MD, FACS

Procedures for Benign Gastric and Duodenal Disease

Advances in the medical management of peptic ulcer disease, including the use of effective acid-suppressing medications (e.g., histamine receptor antagonists and proton pump inhibitors [PPIs]) and the treatment of *Helicobacter pylori*, have led to a dramatic decrease in the need for elective surgical management of uncomplicated duodenal and gastric ulcers. In the past, surgery was the only effective long-term option for peptic ulcer disease, but over the past two decades, it has become an increasingly rare choice.¹ Currently, operative therapy for peptic ulcer disease is largely reserved for the management of complications such as hemorrhage, perforation, and obstruction. The recognition that medical management successfully prevents ulcer recurrence in most patients has caused surgical management of complicated ulcer disease to evolve into a more minimalist strategy that favors damage control surgery for complications and only infrequently resorts to acid-reducing operations.²

In this section of the chapter, we focus primarily on procedures performed to treat peptic ulcer disease, although we also briefly address diverticulectomy for duodenal diverticular disease. Other gastroduodenal procedures for nonmalignant disease are described in more detail elsewhere: gastric restrictive procedures and gastric bypass are discussed in the context of bariatric surgery [see 5:7 *Surgical Treatment of Morbid Obesity*]; choledochoduodenostomy and transduodenal sphincteroplasty are discussed in the context of biliary tract surgery [see 5:22 *Procedures for Benign and Malignant Biliary Tract Disease*]; cystogastrostomy for intractable pancreatic pseudocysts is discussed in the context of pancreatic surgery [see 5:24 *Procedures for Benign and Malignant Pancreatic Disease*]; and duodenal diverticularization is discussed in the context of pancreatic and duodenal trauma [see 7:9 *Injuries to the Pancreas and Duodenum*].

PREOPERATIVE EVALUATION

The appropriate extent of preoperative evaluation for a patient undergoing surgery for a benign gastroduodenal disorder is dictated primarily by the nature of the presenting problem. In the case of gastric outlet obstruction or a rare condition such as intractable peptic ulcer disease that is refractory to medical management, the preoperative workup may be extensive and include detailed endoscopy, contrast studies of the upper abdomen, cross-sectional imaging with computed tomography (CT), and full laboratory panels. In

most cases of complicated peptic ulcer disease, however, the emergency nature of the situation necessarily renders an extensive preoperative workup impractical. For instance, patients with perforated duodenal ulcers typically present in distress with an acute abdomen. A chest x-ray that demonstrates free intraperitoneal air is all that is needed before the patient is taken to the operating room; the decision to proceed to operation should not be delayed by waiting for further images (e.g., CT scans).

Patients who are experiencing upper gastrointestinal (GI) hemorrhage secondary to peptic ulcer disease should undergo endoscopy to identify the source of bleeding [see 5:5 *Gastrointestinal Bleeding*]. In many cases, endoscopic management of bleeding ulcers is possible, rendering surgical management unnecessary. Definitive surgical management is indicated, however, if bleeding leads to hemodynamic instability, an extensive transfusion requirement (i.e., more than 6 units), or rebleeding after initial endoscopic management. Objective criteria for surgery must be determined on a patient-by-patient basis. Precise preoperative localization of the bleeding source is essential; a bleeding posterior duodenal ulcer, for example, cannot be managed in the same way as hemorrhage from diffuse severe gastritis. Endoscopy should therefore be performed whenever possible. Alternatively, if brisk bleeding prevents clear intraluminal visualization of a bleeding site, angiographic localization may be attempted.

Occasionally, patients present for surgery with refractory gastric ulcers. If the ulcer has not healed after 12 weeks of optimal medical therapy, resection is indicated to rule out an occult gastric malignancy. In such cases, the preoperative workup should include endoscopic biopsies of the ulcer base and the surrounding gastric mucosa so that a preoperative diagnosis of malignancy can be made if possible. In view of the concern about a possible gastric malignancy, it is reasonable to obtain a preoperative chest x-ray and a CT scan of the abdomen so as to detect possible nodal or distant metastases.

OPERATIVE PLANNING

Patients undergoing gastroduodenal procedures should receive general anesthesia and have a nasogastric tube and Foley catheter in place. The supine position is preferred. The operation is usually done via an upper midline incision or, occasionally, via a bilateral subcostal incision, with fixed retractors used in either case.

The choice of procedure is primarily dictated by the indication for operation. Usually, several options are available. The first priority is to manage complications (e.g., bleeding and perforation); whether an accompanying acid-suppressing procedure is indicated and which one should be done depend on the clinical setting. Most commonly, duodenal perforation is treated with closure and omental patching, with or without an acid-reducing procedure. A bleeding ulcer is treated with oversewing of the bleeding vessel, with or without an acid-reducing vagotomy and pyloroplasty. Gastric outlet obstruction may be managed with several different approaches, including vagotomy with antrectomy and vagotomy with drainage via pyloroplasty or gastroenterostomy. In the rare cases of intractability, highly selective vagotomy (HSV) is the procedure of choice.

An important component of preoperative evaluation is determination of the severity and duration of disease. If symptoms are long-standing or recurrent—particularly when the patient has already received acid-reducing or anti-*H. pylori* therapy—a definitive acid-reducing procedure should be considered. As has been demonstrated,³ however, ulcer recurrence is significantly reduced even without an acid-reducing procedure when perforated ulcers are managed with anti-*H. pylori* agents in conjunction with a PPI. Therefore, a compliant patient who is presumed to be infected with *H. pylori* may not need to undergo an additional acid-reducing procedure. The evidence for this strategy is less clear with respect to bleeding or obstructing ulcers.

OMENTAL PATCH FOR DUODENAL PERFORATION (GRAHAM PATCH)

Operative Technique

Perforated duodenal ulcers are typically treated by oversewing the perforation and then placing a portion of the greater omentum over the suture line. The duodenal ulcer wall is carefully débrided and closed with three or four interrupted silk sutures; the tails of the sutures may be used to hold the omentum in place. Alternatively, if the ulcer edges are edematous and not expected to close easily, the perforation may be closed with a true Graham patch, which involves plugging the defect with a well-vascularized omental pedicle [see Figure 1]. Care should be taken to avoid tying sutures too tightly; this can lead to devascularization of the omental pedicle. Once the operation has been completed, the abdomen is generously irrigated to remove any contamination, and a search is made for occult collections in the subphrenic space and the pelvis.

Troubleshooting

To avoid placing excessive tension on the repair, primary closure should not be attempted if the duodenal wall is overly edematous and thickened. For large perforations that are expected to result in gastric outlet obstruction if closed, consideration should be given to incorporating the closure into a pyloroplasty.

There is some controversy regarding whether an acid-reducing operation should be added to the omental patch procedure. If the patient is stable and has a history of peptic ulcer disease, a definitive ulcer operation is included; HSV may be preferable to truncal vagotomy and pyloroplasty in that it is less likely to give rise to dumping syndrome and postvagotomy diarrhea. If the patient has no history of peptic ulcer disease, has a severe medical illness, is hemodynamically unstable, has a long-standing perforation, or exhibits gross abdominal contamination, a definitive ulcer operation is omitted. In cases

Figure 1 Omental (Graham) patch. Three or four interrupted sutures are placed along the ulcer edge. If possible, the ulcer is closed primarily and reinforced with omentum. Primary closure may be difficult; in a true Graham patch, primary closure is not attempted, and omentum is used to cover the tissue defect.

of gross contamination of the abdomen, it is probably inappropriate to divide the peritoneum over the esophagus during vagotomy and thereby expose the mediastinum to infection.

Complications

Persistent leakage should be uncommon after adequate closure. Duodenal scarring at the area of perforation and repair may lead to gastric outlet obstruction. Incomplete exploration and irrigation of the abdomen may result in late infection.

Outcome Evaluation

With adequate acid suppression and anti-*H. pylori* therapy, symptoms of duodenal ulcer are unlikely to recur. The 1-year recurrence rate after omental patching is substantially lower when both therapies are employed than when only a PPI is given (5% versus 38%).³

VAGOTOMY AND PYLOROPLASTY FOR BLEEDING DUODENAL ULCER

Truncal vagotomy with pyloric drainage via pyloroplasty is rarely employed as primary therapy for peptic ulcer disease, but it does play a role in emergency management of bleeding duodenal ulcers. This approach to acid suppression fits well with the proximal duodenotomy used to control the hemorrhage. Exposure of the first portion of the duodenum via a longitudinal incision in the pylorus is combined with truncal vagotomy; the pylorus is then closed in a transverse fashion to prevent the development of gastric outlet obstruction.

Operative Technique

Step 1: exposure and pyloric division A Kocher maneuver is performed. The pylorus is identified through palpation and through identification of the pyloric vein as it courses anteriorly. Two traction sutures are placed in the anterior aspect of the pylorus, one superiorly and one inferiorly.

A longitudinal incision is made that extends approximately 2 to 3 cm on either side of the pylorus.

Step 2: ligation of bleeding vessel The bleeding ulcer bed is directly oversewn with at least three sutures. Figure-eight sutures are placed on the superior and inferior borders of the ulcer bed to ligate the gastroduodenal artery proximal and distal to the ulcer, and a third figure-eight suture is placed medially to control the transverse pancreatic branch [see Figure 2].

Step 3: pyloroplasty Tension is applied to the previously placed traction sutures to convert the longitudinal incision to a transverse one. The incision is then closed transversely in two layers with full-thickness bites of 3-0 or 2-0 nonabsorbable suture material (Heineke-Mikulicz pyloroplasty) [see Figure 3]. Tension-free closure is facilitated by adequate duodenal mobilization (by means of the Kocher maneuver) and lysis of surrounding adhesions.

Step 4: vagotomy To perform the vagotomy, further exposure may be needed, including mobilization of the left lateral section of the liver and division of the triangular ligament. Downward traction on the greater curvature of the stomach is essential to apply gentle tension to the esophagogastric junction and the proximal vagi. The peritoneum over the esophagus is divided transversely with the electrocautery; exposure may be facilitated by surrounding the distal esophagus with a Penrose drain for downward traction. The left (anterior) vagus is best identified by applying traction to the right and posteriorly so that the nerve can be traced into the posterior mediastinum. All fibers entering the distal esophagus are divided. The main nerve trunk is clipped proximally and distally, and a 2 cm long segment is excised. The right (posterior) vagus is exposed by applying traction to

Figure 2 Vagotomy and pyloroplasty: sutures. To control a bleeding duodenal ulcer, traction sutures are placed along the cephalad and caudad borders of a longitudinal incision across the pylorus. Figure-eight sutures are placed at the cephalad and caudad portions of the ulcer to occlude the gastroduodenal artery. An additional U-stitch is placed to control small transverse pancreatic branches that may cause late bleeding. Care should be taken to avoid the underlying common bile duct.

the left and anteriorly; the nerve can then be palpated as a taut cord and divided in much the same manner as the anterior vagus. For a complete vagotomy, the distal esophagus must be skeletonized for approximately 5 cm [see Figure 4].

Figure 3 Vagotomy and pyloroplasty. For a Heineke-Mikulicz pyloroplasty, a full-thickness longitudinal incision is made that extends from a point 1 cm proximal to the pylorus to a point 1 to 2 cm distal to the pylorus. The incision is closed transversely in two layers. Superior and inferior stay sutures help align the incision for closure.

Figure 4 Vagotomy and pyloroplasty. For the truncal vagotomy, the peritoneum over the esophagogastric junction is opened wide to afford exposure. Gentle downward traction is applied to the stomach to facilitate identification of the two vagus nerves. Surgical clips are applied to each nerve in turn, and a 2 to 3 cm nerve segment is removed between the clips. These segments should be inspected to confirm removal of neural tissue.

Troubleshooting

As this procedure becomes less frequent and surgeons' experience with it dwindles, location of the vagus nerves may prove an increasingly troublesome task. In most cases, complete skeletonization of the distal esophagus in conjunction with appropriate traction should allow palpation of the main vagal trunks.

If substantial duodenal scarring is present, a tension-free Heineke-Mikulicz pyloroplasty may not be possible, and a Finney pyloroplasty may be preferable. The Finney procedure is essentially a side-to-side anastomosis that is created in two layers between the distal stomach and the proximal duodenum [see Figure 5]. Complete mobilization of the duodenum, including adhesiolysis and a generous Kocher maneuver, is required.

Figure 5 Finney pyloroplasty. If a tension-free Heineke-Mikulicz pyloroplasty is not feasible, a Finney pyloroplasty may be performed instead. (a) The distal stomach and the proximal duodenum are aligned with stay sutures; meticulous lysis of surrounding adhesions is essential. An inverted U-shaped incision is made. (b) The pyloroplasty is created in two layers. The posterior portion of the outer layer, consisting of seromuscular Lembert sutures, is placed first, followed by an inner layer constructed with a continuous full-thickness absorbable suture. (c) The anterior portion of the inner layer is closed with a continuous full-thickness suture. Some surgeons prefer a Connell suture at this site. (d) The anterior portion of the outer layer, consisting of silk Lembert sutures, is placed.

Care should be taken to keep from injuring the common bile duct (CBD), particularly when the vascular inflow to a deeply penetrating duodenal ulcer is being sutured.

Complications

Leakage from a pyloroplasty is rare. Gastric outlet obstruction may occur secondary to either scarring or edema at the operative site; often it is relieved by nasogastric decompression and conservative management. The incidence of ulcer recurrence and rebleeding is quite low with adequate anti-*H. pylori* treatment.

ANTRECTOMY

The primary indication for gastric resection in the setting of peptic ulcer disease is chronic obstruction caused by scarring, typically from a pyloric channel ulcer. Antrectomy removes the gastrin-secreting portion of the stomach. In addition, antrectomy may be required for recurrent bleeding after an adequate vagotomy and pyloroplasty for a bleeding duodenal ulcer. Alternatively, antrectomy may be the elective operation of choice for intractable type I, II, and III gastric ulcers, as well as a primary emergency surgical option for perforated or bleeding gastric ulcers. Historically, a primary Billroth I gastroduodenostomy has been the preferred procedure, but surrounding scar tissue may limit the mobility of the duodenum, in which case, a Billroth II gastrojejunostomy may be required for a tension-free anastomosis. Antrectomy is typically combined with truncal vagotomy.

Operative Technique

Step 1: exposure The lesser sac is entered via the avascular plane in the greater omentum, the plane between the stomach and the pancreas is developed, and the lesser omentum is divided. The proximal border of the antrum must be identified before the stomach is divided. On the greater curvature, the antrum extends to a point between the pylorus and the fundus; on the lesser curvature, it extends to a point just above the incisura. Distally, the dissection is carried past the pylorus. Along the lesser curvature, dissection necessitates division of the descending branch of the left gastric artery, as well as the right gastric artery. Dissection along the pylorus must be meticulous to ensure that the pancreas is not damaged. If a Billroth I anastomosis is planned, dissection should continue 1 cm beyond the pylorus to expose a sufficient length of duodenum for the anastomosis. If a Billroth II reconstruction is planned, dissection need extend only far enough to allow division of the duodenum past the pylorus.

Step 2: division of stomach A gastrointestinal anastomosis (GIA) stapler is used to divide the stomach at the estimated borders of the antrum. The antrum is gently retracted anteriorly and to the patient's left. The right gastroepiploic artery and vein are divided just distal to the pylorus. The duodenum is then divided distal to the pylorus with a transverse anastomosis (TA) stapler.

Step 3: reconstruction When feasible, a Billroth I reconstruction (primary gastroduodenostomy) may be performed to maintain physiologic antegrade flow (although there are no data establishing that this maintenance of antegrade flow is beneficial). In addition, this reconstruction avoids the complications associated with a Billroth II reconstruction (e.g., afferent and efferent loop syndromes and

duodenal stump leaks). A generous Kocher maneuver, if not already performed, is necessary to minimize tension on the anastomosis. The lower portion of the staple line is removed for the width of the duodenal stump, and the anastomosis is performed in two layers or fashioned with a GIA stapler through a gastrotomy [see Figure 6].

If a primary gastroduodenostomy is not possible, a Billroth II reconstruction (gastrojejunostomy) is indicated. This procedure involves a number of technical considerations: management of the duodenal stump, the length and placement of the afferent limb, and the placement and method of the anastomosis. If the duodenum is not scarred or inflamed, simple staple closure will suffice; if closure proves difficult, a lateral duodenostomy tube may help decompress the stump. The duodenal stump should be covered with an omental patch.

The segment used for the anastomosis should be as short as possible while still being able to reach the stomach without tension; approximately 20 cm of proximal jejunum should be sufficient to serve as the afferent limb. Passing the jejunum through a retrocolic window places less tension on the mesentery than an antecolic approach does, although gastric emptying will occur with either method. If a retrocolic approach is used, a window is created for the jejunum; this must be closed and fixed to the small bowel.

The gastrojejunostomy may be constructed either to the posterior wall of the stomach or to the inferior portion of the excised staple line. If the anastomosis is placed at the gastric staple line, the inferior portion of the staple line is excised, often together with a wedge of stomach behind the staple line. A two-layer anastomosis is created with an outer layer of Lembert sutures and an inner layer of absorbable full-thickness

Figure 6 Antrectomy: Billroth I reconstruction (gastroduodenostomy). (a) The anastomosis is done in two layers. The inner layer is constructed by placing a continuous full-thickness suture. (b) The outer layer is constructed with silk Lembert sutures. The junction of the anastomosis and the gastric staple line has been referred to as the angle of sorrow, a term that reflects the common complication of leakage at the intersection of suture or staple lines. This junction may be reinforced with additional Lembert sutures.

sutures; the gastric staple line may be oversewn [see Figure 7]. Alternatively, the gastrojejunostomy may be created by means of stapling. A GIA stapler is introduced via a gastrotomy and a small enterotomy, and the defect is subsequently closed with a TA stapler. Additional reinforcement is not necessary for this staple line.

Some authors recommend the use of a Braun enteroenterostomy between the efferent and afferent limbs to reduce bile reflux and decompress the duodenal stump [see Figure 8a]. Staple closure of the afferent limb above the enteroenterostomy may also be performed to limit bile reflux into the stomach; this measure creates a configuration referred to as an uncut Roux-en-Y [see Figure 8b]. Enteroenterostomy at this site may also be performed on an emergency basis to treat afferent limb syndrome. Staple closure of the afferent limb may discourage bile reflux, with the effect of limiting bile reflux gastritis and esophagitis.⁴

Troubleshooting

In most instances, a noninflamed duodenum can readily be closed with a TA stapler. However, the thickened and inflamed tissue present in the setting of inflammation with duodenal perforation is not amenable to easy closure. Furthermore, poor afferent limb drainage can lead to increased pressure in the afferent limb, thus contributing to leakage. Lateral duodenostomy tubes may be used for decompression. The duodenum should be sutured to the abdominal wall in a Stamm fashion at the exit site of the tube. Alternatively, if the duodenum cannot be closed without significant tension, closure may be accomplished around a red rubber or mushroom

catheter. For especially thick tissue, primary suture closure is preferable to staple closure. Inversion of the duodenal suture line with Lembert sutures is not necessary. In addition, omental patch reinforcement of the duodenal stump may be desirable.

Some surgeons report success with a retrograde duodenostomy tube. If sufficient afferent limb of jejunum is available to reach the abdominal wall prior to the gastrojejunostomy, a soft duodenostomy tube may be passed from this site in a retrograde manner past the ligament of Treitz to the second portion of the duodenum. Although this tube is potentially more difficult to place than a lateral duodenostomy tube, eventual removal and closure are thought by some to be easier and may avoid persistent duodenal fistula.

Complications

Leakage from the duodenal stump is a potentially devastating complication that necessitates prompt reoperation, wash-out, and drainage. The diagnosis of duodenal stump leakage is confirmed by aspirating bilious fluid from a right upper quadrant fluid collection or by performing a technetium-99m—labeled hepatiminodiacetic acid scan.

Duodenal leaks can rarely be closed primarily. Duodenostomy may be indicated to further decompress the afferent limb and prevent continuous leakage. The goals are to create a controlled fistula to the skin and to prevent the accumulation of biliary fluid in the abdomen.

Delayed gastric emptying after gastrojejunostomy may occur and is generally managed conservatively. On rare occasions, reoperation is required for delayed anastomotic function.

Figure 7 Antrectomy: Billroth II reconstruction (gastrojejunostomy). (a) The inferior portion of the gastric resection line is excised, along with a small wedge of the stomach. (b, c) A two-layer anastomosis is created, with an outer layer of Lembert sutures and an inner layer of full-thickness absorbable sutures. The upper gastric staple line may be oversewn with interrupted Lembert sutures.

Figure 8 Braun enteroenterostomy. Antrectomy: Billroth II reconstruction (gastrojejunostomy). (a) A Braun enteroenterostomy facilitates decompression of the afferent limb in a Billroth II gastrojejunostomy. It may be done as either a sutured or a stapled anastomosis. (b) An option is to close the afferent limb above the enteroenterostomy with a transverse anastomosis stapler (so that the jejunal lumen is occluded but not divided). This configuration, often referred to as an uncut Roux-en-Y, temporarily discourages, but does not prevent, reflux of bile into the stomach.

In the case of a Billroth I reconstruction, takedown of the anastomosis is associated with devascularization and duodenal stump leakage. It is therefore preferable to leave the anastomosis in place and perform a gastrojejunostomy along the greater curvature of the stomach. In the case of a Billroth II reconstruction, revision may be required for better positioning of the anastomosis.

Afferent limb obstruction may occur as a consequence of adhesions, internal herniation, volvulus, or a kink at the angle formed with the gastric remnant. Obstruction to outflow of the afferent limb creates a closed-loop obstruction, with persistent secretion of bile and pancreatic fluids into the loop. Such obstruction often presents as recurrent pancreatitis. The diagnosis is facilitated by CT scanning; if it is confirmed, prompt exploration is mandated. Correction of the obstruction may necessitate conversion to a Roux-en-Y reconstruction, shortening of the afferent limb, or a side-to-side enteroenterostomy with the efferent limb (see above).

Bleeding, generally in the form of intraluminal blood loss, is a frequent occurrence after gastrectomy. A bloody aspirate from the nasogastric tube is a common presentation. If bleeding persists for more than 5 days after the initial operation, endoscopy with endoscopic coagulation or epinephrine injection may be considered. Endoscopic approaches should be undertaken with care to minimize the risk of distending the new anastomosis.

Alkaline reflux gastritis is one of the most common long-term complications of gastrectomy, developing in 5 and 15%

of patients after gastric surgery.⁵ This complication is most frequently associated with Billroth II reconstructions. Although reflux is common, symptoms (e.g., epigastric pain, nausea, and bilious emesis) are relatively rare. Medical management is generally ineffective. If surgery is required, conversion of the Billroth II reconstruction to a Roux-en-Y reconstruction is indicated. In those patients who have a Roux-en-Y rather than a Billroth II reconstruction, the preferred treatment is to divert alkaline contents to a location 45 to 60 cm beyond the gastric remnant.

HIGHLY SELECTIVE VAGOTOMY

Although both vagotomy with antrectomy and vagotomy with pyloroplasty drainage provide relief from duodenal ulcers, they are also associated with significant complications, including dumping syndrome, diarrhea, bile reflux, and poor gastric emptying. Highly selective vagotomy, also referred to as parietal cell vagotomy, was developed with these complications in mind; the idea was to avoid vagal denervation of viscera other than the parietal cell mass while keeping the pylorus mechanically and functionally intact.^{6,7} HSV was found to reduce post-vagotomy diarrhea and dumping dramatically; however, it was also found to be associated with a much higher rate of recurrent ulceration (greater than 10% at 5 years). Today, in an era characterized by greatly improved medical management of peptic ulcer disease, most GI surgeons rarely perform HSV, if at all. One possible use for this procedure in the current context might be to treat intractable ulcer disease in young patients.

Operative Technique

Step 1: exposure and gastric mobilization Wide exposure is obtained with the help of upward retraction on the costal margin. The gastrocolic omentum is entered outside the gastroepiploic vessels to preserve the blood supply to the greater curvature. Adhesions to the peritoneum over the pancreas are divided sharply, and the stomach is rotated upward to allow visualization of the posterior leaf of the lesser omentum and the posterior nerve of Latarjet, which runs adjacent to the descending branch of the left gastric artery.

Step 2: dissection of anterior and posterior nerve branches to lesser curvature The distal branches of the nerve of Latarjet are defined, with care taken to preserve the so-called crow's foot, which is typically located near the incisura angularis, approximately 6 to 7 cm proximal to the pylorus. Gentle downward traction is applied to the stomach, the left gastric vascular arcade is identified, and all tissue between this arcade and the lesser curvature is divided and ligated. The dissection therefore includes individual branches of the vagus nerve to the stomach. It should proceed upward as far as the esophagogastric junction. The posterior branches are approached either by rotating the stomach or by proceeding directly through the lesser omentum [see Figure 9].

Step 3: dissection of esophagogastric junction The distal esophagus is cleared of all nerve fibers for a distance of approximately 5 cm above the esophagogastric junction. The dissection must stay close to the lesser curvature and the esophagus, avoiding the tissues to the right of the esophagus,

where the main vagal trunks lie. The posterior esophagogastric junction is exposed by means of gentle traction and slight rotation of the distal esophagus. Exposure is facilitated by downward traction provided by a Penrose drain placed around the esophagogastric junction.

Troubleshooting

Incomplete denervation of the parietal cell mass is prevented by paying meticulous attention to dissection, particularly at the esophagogastric junction. The left side of the distal esophagus must be manually stripped so that the so-called criminal nerve of Grassi can be identified and ligated. About 4 to 5 cm of the distal esophagus should be stripped of vagal input.

Complications

The primary complication of HSV is recurrent ulceration. The reported rates vary, but the general view is that the 5-year ulceration recurrence rate may be higher than 10%.⁸ Most recurrent ulcers occur in the setting of incomplete vagal denervation. Given the small number of patients for whom HSV is indicated, few GI surgeons are likely to have accumulated sufficient experience with this technique to be proficient at it. Fortunately, most recurrent ulcers can now be managed medically, and few call for surgical management.

LAPAROSCOPIC TREATMENT OF PEPTIC ULCER DISEASE

Numerous reports of laparoscopic approaches to truncal vagotomy and HSV have been published over the past two decades. The laparoscopic versions of these procedures proceed in much the same way as the traditional open versions. In a laparoscopic HSV, the ultrasonic shears are frequently used to divide the anterior and posterior vagal branches to the lesser curvature from the crow's foot to the esophagogastric junction. Mixed procedures that combine posterior truncal vagotomy with more selective anterior gastric denervation are common. In the Taylor procedure, an anterior seromyotomy is performed from the angle of His to the crow's foot, and the seromuscular layers are subsequently closed primarily.⁹ A variant of the laparoscopic Taylor procedure includes an anterior linear gastrectomy, in which a linear strip of the stomach wall is removed parallel to the lesser curvature with an endoscopic GIA stapler. This procedure seems to be functionally equivalent to HSV. The majority of the studies of laparoscopic vagotomy, however, have been individual case series that do not compare the laparoscopic approach with a traditional open approach. Undoubtedly, the scarce comparative data reflect the declining indications for vagotomy for intractable peptic ulcer disease. Thus, although laparoscopic HSV has been well described, it is by no means clear that it should be recommended over open HSV for those rare patients in whom this procedure is indicated.

More data are available on laparoscopic treatment of perforated duodenal ulcers. A meta-analysis of 13 studies comparing laparoscopic and open approaches to perforated peptic ulcers found that laparoscopic repair yielded excellent results, albeit with a small but insignificant increase in the reoperation rate.¹⁰ The laparoscopic approach is therefore considered as safe and effective as open Graham patch repair.

Figure 9 Highly selective vagotomy. Anterior and posterior branches of the nerve of Latarjet to the lesser curvature are ligated and divided. The distal branches, comprising the so-called crow's foot, are left intact. The posterior branches may be approached via the lesser omentum.

The procedures generally involve either suture closure of the perforation followed by omentopexy or omentopexy alone and should be attempted only by surgeons with advanced laparoscopic skills. The threshold for conversion to an open procedure should be low if the ulcers are particularly large ulcers or prove difficult to localize.

DUODENAL DIVERTICULECTOMY

Incidental duodenal diverticula are common. Such diverticula consist of a sac that includes only mucosa and submucosa, and most occur within 2 cm of the ampulla of Vater. Complications include ulceration and bleeding, compression of the CBD with cholangitis or pancreatitis, and, in cases of perforation, abscess formation with peritonitis. CT scanning is useful for differentiating this condition from cholecystitis or pancreatitis. Surgery is rarely required; it is indicated primarily for complications such as bleeding, perforation, and biliary or duodenal obstruction.

Operative Technique

The main surgical options are simple diverticulectomy with drainage and transduodenal diverticulectomy (as described by Iida¹¹). If the duodenum is free of inflammation, the transduodenal approach is preferred because it minimizes the need for dissection of the diverticulum from the surrounding pancreas. However, if the diverticulum does not involve the pancreas, simple excision flush with the duodenal wall, followed by closure in two layers, may be sufficient. The ensuing technical description focuses on transduodenal diverticulectomy.

Step 1: exposure and duodenotomy A generous Kocher maneuver is performed to elevate the head of the duodenum. The duodenum is then opened by making a 4 cm longitudinal incision along the antimesenteric border, and the ampulla is either visualized or palpated. To identify the ampulla, it may be necessary to place a catheter into the CBD via a separate choledochotomy.

Step 2: diverticulectomy The orifice of the diverticulum is identified, and the mucosa is inverted into the lumen of the duodenum. The neck of the diverticulum is transected 2 mm from the junction with the duodenal wall. The diverticular opening is then closed with interrupted seromuscular Lembert sutures of 3-0 silk and interrupted mucosal sutures of 4-0 polyglactin. The duodenum is closed in two layers, also with an inner layer of 4-0 polyglactin and an outer layer of seromuscular Lembert sutures of 3-0 silk. Closed-suction drainage adjacent to the duodenum is indicated.

Special case: perforated duodenal diverticulum In the setting of acute inflammation, duodenotomy is avoided. Instead, the abscess is evacuated, and the diverticulum is excised along with just enough of the adjacent duodenal wall to ensure that only healthy tissue is left. If the resulting duodenal defect is large, either sleeve resection of the duodenum or drainage of the open duodenal defect into a Roux-en-Y jejunal limb may be required.

Troubleshooting

Inadvertent closure of the CBD may be prevented by inserting a catheter into the duct. If the duodenum is markedly inflamed, suture line breakdown is likely, eventually leading to a duodenal fistula. The area can be isolated by means of

pyloric exclusion or antrectomy with Billroth II reconstruction. In addition, bile flow can be diverted by performing a choledochojejunostomy to a Roux-en-Y intestinal limb to prevent combined leakage of pancreatic fluid and bile.

Diverticula arising from the third or the fourth portion of the duodenum may be approached via the transverse mesocolon and may be excised either primarily or via a transduodenal approach. Inverting the diverticulum without excising it is not recommended, because it may lead to duodenal obstruction.

Procedures for Gastric Cancer

Surgical resection remains the primary therapeutic modality for gastric cancer [see 5:8 *Tumors of the Stomach, Duodenum, and Small Bowel*]. The diagnosis of gastric cancer is primarily made by means of endoscopy with biopsy. Numerous considerations must be addressed before operation, including the stage of the cancer on diagnostic imaging, the use of staging laparoscopy, the extent of the planned gastrectomy, the extent of the planned lymphadenectomy, the placement of feeding enterostomies, and the patient's overall medical fitness for surgery.

PREOPERATIVE EVALUATION

Endoscopy, with or without endoscopic ultrasonography (EUS), is essential for diagnosis. Preoperative biopsy is helpful for confirming the suspected pathologic process, particularly because the extent of resection will be different if a less common lesion, such as a gastrointestinal stromal tumor (GIST), is identified. Endoscopic localization is critical because the extent of the gastrectomy will depend on the precise location of the tumor. It should be noted, however, that the true location of the tumor, as determined at laparotomy, may differ significantly from the preoperative estimate made on the basis of endoscopy. Abdominal CT and chest radiography are indicated to rule out obvious metastatic disease, which would be an indication for a more conservative surgical approach or even for nonoperative therapy. The preoperative physical examination should also focus on the detection of occult metastatic disease, concentrating on such sites as the supraclavicular lymph nodes and the pouch of Douglas. A bone scan is indicated if metastasis to bone is suspected. Laparoscopic staging (see below) may be performed to identify occult metastatic disease (and, possibly, to prevent an unnecessary laparotomy in an otherwise ill patient).¹² If the tumor is not bleeding or causing an obstruction, palliative resection might be avoided. Generally, curative surgery should be attempted only when the tumor is believed to be limited to the stomach and the perigastric lymph nodes. On occasion, however, curative intent surgery may be considered for tumors that involve nearby resectable structures (e.g., the transverse colon), provided that these structures can be removed en bloc with the primary lesion.

In Japan, where gastric cancer is among the leading causes of cancer-related death, screening endoscopy is widespread and early gastric cancer is identified with some frequency. In Western countries, however, screening endoscopy has not been implemented because of the lower incidence of gastric cancer and hence the lower utility of screening. It is therefore not uncommon for patients to present with more advanced

cancers. Accordingly, although procedures such as wedge resection for early gastric cancer have been described, most gastric cancer patients in the United States require formal gastrectomy and lymphadenectomy.

OPERATIVE PLANNING

Extent of Resection

The extent of the resection required for treatment of a gastric malignancy is determined primarily by the preoperative pathologic diagnosis and the site of the tumor. Considerably smaller surgical margins are required for rare mesenchymal tumors (e.g., GISTs) than are necessary for gastric adenocarcinomas, which tend to spread microscopically well beyond the gross extent of the tumor. Most mesenchymal tumors can be adequately treated with a wedge resection or partial gastrectomy that achieves a 1 cm gross margin. Laparoscopic approaches to such tumors have been described that employ either the endoscopic GIA stapler or excision with suture closure [see Laparoscopic Resection of Malignant Gastric Tumors, *below*]. Such approaches may be facilitated by endoscopic tattooing of an appropriate margin or by intraoperative endoscopic guidance. For adenocarcinomas, a margin of at least 5 cm is recommended.

A 5 cm margin may be particularly difficult to achieve when the tumor is located along the lesser curvature. In many such cases, although the tumor appears to be distal and possibly amenable to a subtotal gastrectomy, a 5 cm negative margin along the lesser curvature would place the proximal resection margin far above the incisura angularis and near the esophagogastric junction, thus necessitating total or near-total gastrectomy. For lesser-curvature tumors whose location allows adequate margins to be obtained, distal gastrectomy with Billroth II gastrojejunostomy is preferred; for more proximal tumors, total gastrectomy with esophagojejunostomy may be required.

Special consideration must be given to tumors of the esophagogastric junction. In the classification scheme described by Siewert and Stein,¹³ such tumors are defined as lying within 5 cm of the anatomic esophagogastric junction in either direction along the craniocaudal axis of the esophagus and the stomach. They are classified into three types as follows:

1. Type I: the center of the tumor lies 1 to 5 cm proximal to the esophagogastric junction
2. Type II: the center of the tumor lies within 1 cm of the esophagogastric junction proximally or within 2 cm distally
3. Type III: the center of the tumor lies 2 to 5 cm distal to the esophagogastric junction

It is generally agreed that total esophagectomy is required for type I esophagogastric junction tumors [see 4:7 *Open Esophageal Procedures*]. The necessary extent of resection for type II and III esophagogastric junction tumors has been more controversial. A microscopically negative (R0) surgical margin is closely associated with survival after resection of esophagogastric junction adenocarcinomas, although R0 resection can be quite difficult to achieve, given the propensity of these tumors for intramural spreading. In our experience, positive margins have not been found in patients with T1 or T2 tumors, even when the margins are smaller than

4 cm. In patients with T3 or T4 tumors, however, proximal margins of at least 6 cm have proved necessary. For T1 and T2 tumors, total gastrectomy without thoracotomy may yield adequate margins. For T3 and T4 tumors, however, extended gastrectomy with thoracotomy or esophagectomy may be required.¹⁴ It is well documented that the margin lengths measured on prefixed esophageal specimens are only about 50% of the corresponding lengths measured in situ before completion of resection.¹⁵ Accordingly, intraoperative decisions about the extent of resection should be based on margin length requirements that may be considerably greater than those derived from resection specimens.

Extent of Lymphadenectomy

The extent of lymphadenectomy with gastrectomy, in terms of not only the gross number of lymph nodes examined but also the particular nodal basins sampled, has been the subject of considerable debate. Regional nodes are classified as N1 (perigastric), N2 (along the splenic and left gastric arteries and at the celiac axis), N3 (along the hepatoduodenal ligament and the root of mesentery), and N4 (para-aortic and middle colic nodes). Alternatively N2 nodes have been variously reported as groups N2–N4 above, including splenic, left gastric, celiac, hepatoduodenal, mesenteric, and para-aortic nodes. Since the 1960s, Japanese surgeons have advocated extended dissection of lymph nodes to improve outcomes in gastric cancer.¹⁶ Whereas a D0 resection represents incomplete dissection of the N1 nodes, D1 resection involves complete resection of the N1 nodes, and D2 involves complete resection of both N1 and N2 nodes. Western and European authors, however, have not demonstrated the benefit of extended lymphadenectomy in gastric cancer.¹⁷ Outside Japan, surgeons have therefore typically limited lymphadenectomy to the perigastric (D1) lymph nodes. Surgeons in Japan, however, have tended to prefer a much more radical lymph node dissection that includes the second-order (D2) nodes [see Figure 10]. It has not been clear whether more extensive lymph node dissection actually provides a survival benefit or simply improves surgical staging. To date, four randomized, controlled trials have failed to show any significant benefit from extended lymph node dissection. In the largest such study, performed by the Dutch Gastric Cancer Group, more than 700 patients were randomly assigned to undergo either D1 or D2 lymphadenectomy.¹⁸ The 5-year survival rate was essentially the same in the two groups; perioperative morbidity and mortality were significantly higher after D2 lymphadenectomy.

A subsequent study from the same group found that at 10 years after operation, D2 lymphadenectomy provided a benefit (in terms of lower local recurrence) only in the subgroup with positive second-order nodes; however, these patients could not be identified preoperatively.¹⁹ For the cohort as a whole, extended lymph node dissection generated no long-term survival benefit. Therefore, although some surgeons extend the lymphadenectomy to include lymph nodes along the left gastric, celiac, and common hepatic arteries (a so-called D1+ dissection), the standard of care for surgeons in the United States continues to be a D1 lymphadenectomy that includes all perigastric lymph nodes and the greater omentum.

Furthermore, the minimum number of lymph nodes for gastric cancer staging has been evaluated. It has been suggested

Figure 10 Illustrated are the differences between a D1 lymphadenectomy and a D2 lymphadenectomy for gastric cancer. (a) A D1 lymphadenectomy is accomplished by removing the perigastric lymph nodes with the resection specimen; these nodes include those along the right and left cardia (1, 2), those along the lesser curvature (3), those along the greater curvature (4), the suprapyloric nodes (5), and the infrapyloric nodes (6). (b) A D2 lymphadenectomy involves a more radical resection specimen, which includes nodes along the left gastric artery (7), the common hepatic artery (8), the celiac artery (9), the splenic hilum (10), the splenic artery (11), the hepatoduodenal ligament (12), the posterior pancreas (13), the root of the mesentery (14), the transverse mesocolon (15), and the aorta (16).

that a minimum of 15 lymph nodes must be removed during gastrectomy. In a study published in 2000, 5-year survival rates were significantly lower in patients with fewer than 15 lymph nodes sampled than in those with 15 or more lymph nodes examined.²⁰ This decreased survival with fewer sampled lymph nodes was attributed primarily to understaging as the result of inadequate lymphadenectomy.

TOTAL GASTRECTOMY

Operative Technique

Step 1: incision and exposure The abdomen is entered via a midline or bilateral subcostal incision. If a subcostal incision is used, it may have to be extended past the xiphoid process in the midline for optimal exposure. Thorough

exposure of the peritoneal cavity (including the liver, all peritoneal surfaces, and, in women, the ovaries) is undertaken to search for signs of metastatic disease. If the patient has a proximal lesion near the gastric cardia, a thoracotomy may be needed if the distal thoracic esophagus is to be included in the resection specimen. If an incision into the thoracic cavity is being considered, the left chest should be surgically prepared at the time of initial draping to allow extension of the incision across the lower left costal margin if desired. In this setting, if thoracotomy is possible, preoperative placement of a double-lumen endotracheal tube should be considered. The abdominal portion of a thoracoabdominal incision should be performed first to allow assessment of resectability.

Step 2: dissection of omentum from colon The omentum is separated from the colon with an electrocautery or scissors through the relatively avascular plane. Gentle upward traction is placed on the omentum to facilitate entry into the correct surgical plane [see Figure 11]. If the procedure involves a formal D2 lymph node dissection, this is also a convenient time to enter the anterior leaf of the transverse mesocolon, which is resected with the anterior covering of the pancreas. (As noted, most US surgeons perform a D1 resection or some modification thereof and thus do not dissect the anterior peritoneal surface of the mesocolon and pancreas.)

With the dissection starting on the right side, the right gastroepiploic artery is identified and ligated where it originates from the gastroduodenal artery. The short gastric vessels are divided as the dissection proceeds along the greater curvature. The lesser omentum is also divided near the liver and is included with the specimen; care should be taken to identify an aberrant left hepatic artery in the lesser omentum (if present). The dissection is continued onto the peritoneal surface of the distal esophagus.

Step 3: division of duodenum The duodenum is divided just distal to the pyloric ring either with a GIA stapler or with a TA stapler applied twice [see Figure 12]. The right gastric artery is identified and ligated near its base. Division of the duodenum allows elevation and rotation of the stomach, thereby facilitating access to the left gastric artery and the surrounding node-bearing tissue.

With the stomach gently retracted upward and anteriorly, dissection identifies the celiac axis and the left gastric artery [see Figure 13]. The origin of the left gastric artery is ligated and divided, and a suture ligature is placed on the proximal end.

Figure 11 Total gastrectomy: dissection. The omentum is dissected from the transverse colon with scissors or the electrocautery. In the course of this dissection, the right gastroepiploic artery is encountered near the pylorus and divided near its base at the gastroduodenal artery. The dissection continues along the greater curvature, including ligation of the short gastric vessels. In a formal D2 lymphadenectomy, the anterior leaf of the transverse mesocolon and the anterior capsule of the pancreas are dissected. In a D1 lymphadenectomy, these structures are left intact.

Figure 12 Total gastrectomy: division of duodenum. The duodenum is divided just beyond the pylorus with a gastrointestinal anastomosis or transverse anastomosis stapler. The duodenal staple line may be reinforced with interrupted Lembert sutures.

Figure 13 Total gastrectomy: division of left gastric vessels. The stomach is retracted cephalad to expose the left gastric vessels, which may be divided and suture-ligated on the proximal side. Division of the distal esophagus should be preceded by placement of several stay sutures on the proximal esophagus to prevent it from retracting into the posterior mediastinum.

A standard D1 lymphadenectomy does not include splenectomy and distal pancreatectomy. The spleen and pancreas are left in situ and are separated from the resection specimen by dividing and ligating the short gastric vessels (see above). The D2 lymphadenectomy as originally described includes stripping the peritoneum along the anterior pancreas, as well as removing nodes along the splenic artery and, if needed, performing splenectomy and distal pancreatectomy to sample the splenic hilar lymph nodes.

Troubleshooting Leakage from the duodenal stump is a potentially disastrous complication. If the stapled duodenum appears to be ischemic, the staple line may be inverted with Lembert sutures of 3-0 silk.

Step 4: inclusion of necessary lymph nodes The degree of dissection to be performed in the porta hepatis depends on the extent of the planned lymphadenectomy. A D1 lymphadenectomy does not require any of the lymph nodes in this area, but a D1+ lymphadenectomy includes lymph nodes along the common hepatic artery. Gentle left lateral traction is placed on the stomach before division of the left gastric artery to apply some tension to the hepatic artery. The dissection proceeds along the celiac and hepatic arteries to the porta hepatis. The tissue surrounding the common hepatic artery and the left gastric artery is swept medially with the specimen. To sample splenic artery nodes, the peritoneum over the anterior border of the pancreas is divided if not previously removed as part of a planned D2 dissection. Nodal tissue along the splenic artery is visualized and sampled.

Step 5: division of esophagus The peritoneum is divided over the anterior esophagus, and the esophagus is completely dissected free of surrounding tissue. The esophagus is then divided either with a TA stapler or with a scalpel after the placement of a noncrushing bowel clamp. To keep the stump from retracting too far proximally, stay sutures of 2-0 silk should be placed in the proximal esophagus before division. Alternatively, the specimen may be left attached and used as a handle to retract the proximal esophagus inferiorly. The esophagus may then be divided after placement of the posterior suture line. Evaluation of the proximal resection margin with frozen-section analysis is advisable.

Troubleshooting The proximal margin may be found to harbor malignancy; if so, reresection of the proximal margin should be performed. Placement of stay sutures in the proximal esophagus is important; if this is not done, the retracting esophagus may migrate into the posterior mediastinum.

Step 6: reconstruction via esophagojejunostomy The options for reconstruction after gastrectomy include stapled end-to-side esophagojejunostomy, hand-sewn end-to-side esophagojejunostomy, side-to-side esophagojejunostomy, and anastomosis to a jejunal pouch. A Roux-en-Y jejunal limb is fashioned; to prevent biliary reflux, it should be at least 40 to 50 cm long. The Roux limb is then brought up behind the colon to the esophagus. Some authors recommend antecolic placement of the Roux limb to prevent obstruction in the setting of recurrent disease; however, retrocolic placement may facilitate a more tension-free anastomosis.

For a stapled end-to-side esophagojejunostomy, a purse-string suture of 3-0 or 2-0 polypropylene is placed in the esophagus and used to secure the anvil of an end-to-end

anastomosis stapler. The body of the stapler is placed into the Roux limb, with the tip protruding through the end, and the esophagojejunostomy is created on the antimesenteric border of the jejunum [see Figure 14a]. The open end of the Roux limb is then closed with a TA stapler. To reduce tension on the anastomosis, the staple line may be reinforced with interrupted Lembert sutures of 3-0 silk.

A hand-sewn end-to-side esophagojejunostomy is created in a similar fashion at a point near the end of the Roux limb on the antimesenteric border. The posterior row is placed first, with interrupted 3-0 silk sutures as the outer layer and interrupted full-thickness 3-0 absorbable sutures as the inner layer [see Figure 14b]. The knots are tied on the inside of the bowel. The anterior row is then placed, with an inner layer of interrupted full-thickness 3-0 absorbable sutures and an outer layer of interrupted 3-0 silk sutures. Some surgeons prefer a single-layer anastomosis, either with a continuous suture or with interrupted full-thickness sutures. The available data do not favor either single- or two-layer anastomosis in this setting.

Side-to-side esophagojejunostomy requires a substantial length of intra-abdominal esophagus and necessitates extensive mobilization of the distal esophagus. The jejunum may be sutured to the underside of the diaphragm to relieve tension on the anastomosis.

Some authors report improved postoperative quality of life with a jejunal pouch reconstruction. Although straight esophagojejunostomy is known to be related to intestino-esophageal reflux, the creation of a gastric reservoir has intrinsic appeal but has not been widely accepted. A recent randomized controlled trial comparing straight Roux-en-Y esophagojejunostomy with a jejunal J-pouch, however, suggested significant benefit to creating a gastric reservoir.²¹ Whereas functional results were similar in the first year after surgery, function in years 3 to 5 was significantly improved in patients with a jejunal pouch. For a jejunal pouch, the proximal limb of the Roux-en-Y jejunal limb is folded back on itself for a distance of 10 to 15 cm. The pouch is constructed with an enteric stapling device; esophageal anastomosis may then be constructed via a hand-sewn or stapled technique [see Figure 14c].

Drains are not routinely placed after esophagojejunostomy as drain placement may increase the rate of leakage from the esophagojejunostomy.

Troubleshooting Without a sufficient length of intra-abdominal esophagus, primary reconstruction can be difficult. Full mobilization of the intra-abdominal esophagus is essential. Because the esophagus lacks a serosa, transversely oriented Cushing-type sutures may be preferable to Lembert sutures on the anterior and posterior outer layers of a hand-sewn anastomosis.

Step 7 (optional): feeding enterostomy Many patients with gastric adenocarcinoma become significantly malnourished after gastrectomy. The loss of the gastric pouch may adversely affect their ability to fulfill their caloric requirements in the early postoperative period. To prevent further malnutrition, some authors recommend creating a feeding jejunostomy at the time of total gastrectomy with esophagojejunostomy. The jejunostomy should be placed downstream from the jejunoesophagojejunostomy (i.e., more than 50 cm distal to

Figure 14 Total gastrectomy: reconstruction via esophagojejunostomy. Reconstruction via esophagojejunostomy; options include stapled end-to-side esophagojejunostomy, hand-sewn end-to-side esophagojejunostomy, side-to-side esophagojejunostomy, and anastomosis to a jejunal pouch. (a) In a stapled esophagojejunostomy, the anvil is secured in the esophagus with a purse-string suture, an end anastomosis stapler is inserted through the distal end of the Roux limb, and the anastomosis is created to the antimesenteric side of the bowel. Once the anastomosis is complete, the end of the Roux limb is amputated with a single firing of a gastrointestinal anastomosis stapler. (b) A hand-sewn esophagojejunostomy may be fashioned with interrupted full-thickness sutures (as shown), with a continuous full-thickness suture, or as a two-layer anastomosis. After completion of the posterior row, a sump tube may be placed across the anastomosis into the proximal jejunum. After completion of the anterior row, several reinforcing seromuscular sutures may be placed to reduce tension on the anastomosis. (c) Roux-en-Y jejunal pouch. Roux-en-Y reconstruction using a jejunal J pouch is depicted. The antimesenteric sides of two jejunal loops are connected with linear stapling devices for a distance of 10 to 15 cm. The enterotomy is closed with either a hand-sewn or stapled technique. The jejunal pouch may be used for reconstruction via either stapled or hand-sewn esophagojejunostomy.

the anastomosis). When a feeding enteroenterostomy is indicated, we prefer a Witzel jejunostomy.

Complications

D2 lymphadenectomy has been associated with numerous complications, including increased blood loss, longer operating time, colonic devascularization, pancreatitis, and pancreatic leakage. Although complication rates appear to be acceptably low when the procedure is done by an experienced surgeon, there is still the potential for the benefits of extensive lymphadenectomy to be outweighed by the additional complications. Complications may be reduced by omitting distal pancreatectomy and splenectomy while sampling common hepatic, celiac, and splenic artery nodes (D1+ resection).

Anastomotic leakage at an esophagojejunostomy may lead to postoperative infection. Intra-abdominal leaks may be managed by drainage via percutaneous drains or laparotomy, as well as by proximal nasogastric drainage. High anastomotic leaks may result in contamination of the posterior mediastinum or the pleural space, and thoracotomy or tube thoracostomy may be necessary to achieve external drainage.

Occasionally, bleeding may be substantial enough to necessitate reoperation. In this situation, the gastric remnant may be entered via a transverse incision just proximal to the

anastomosis. As a rule, the bleeding can be successfully controlled by placing simple figure-eight sutures.

DISTAL OR SUBTOTAL GASTRECTOMY

Cancers of the distal stomach or antrum may be addressed by means of a distal gastrectomy. Particular attention should be paid to tumors on the lesser curvature, where obtaining an adequate proximal margin may be a problem [see Operative Planning, Extent of Resection, *above*]. The dissection proceeds as in a total gastrectomy, but without division of the short gastric vessels. The omentum is separated from the transverse colon with the electrocautery, and the entire omentum is taken with the specimen. A 5 cm proximal margin is ideal. Commonly, the stomach is divided at a point inferior to the short gastric vessels and proximal to the incisura angularis.

Additional operative details and comments on postgastrectomy complications are available elsewhere [see Procedures for Benign Gastric and Duodenal Disease, Antrectomy, *above*].

LAPAROSCOPIC STAGING FOR GASTRIC CANCER

The goal of laparoscopic staging before attempted curative resection of gastric carcinoma is to detect occult metastatic disease, the presence of which may affect management. For

example, if laparoscopy reveals peritoneal studding in a patient who does not have symptoms such as bleeding or obstruction, a decision may be made to forgo attempts at resection. In the setting of T2 or T4 tumors, laparoscopic staging has been shown to detect occult metastases in 20 to 30% of patients.¹²

The abdomen is explored with a 30° laparoscope inserted via an umbilical port. To facilitate exposure, additional 5 mm ports may be placed in the right upper and left upper quadrants. If laparoscopic ultrasonography is available, one of the port sites should be 10 mm to allow passage of the ultrasound probe. Any suspicious lesion encountered is sampled and sent for frozen-section analysis.

LAPAROSCOPIC RESECTION OF MALIGNANT GASTRIC TUMORS

Laparoscopic gastrectomy is being performed with increasing frequency. The principles of laparoscopic gastric resection are similar to those of the corresponding open procedure, although extensive lymph node dissections may be considerably more difficult with the minimally invasive approach. In the last several years, laparoscopic distal gastrectomy has been described with increasing frequency for early-stage distal gastric cancers, with early results suggesting equivalent outcomes compared with standard “open” techniques.²²

LAPAROSCOPIC DISTAL GASTRECTOMY

Operative Technique

Step 1: positioning Patients are positioned on a split-leg table to allow one surgeon between the patient’s legs. A 30° laparoscope is preferred. It is useful to include intraoperative gastroscopy to confirm the location of the tumor.

Step 2: exposure The omentum is separated from the colon and divided at the splenic flexure with a laparoscopic energy device such as the Harmonic shears or Ligasure device. The greater omentum is divided medial to the short gastric vessels. Medially, the right gastroepiploic artery and vein are divided individually near their roots using hemoclips.

Step 3: division of duodenum and lesser omentum The duodenum is divided 1 cm distal to the pylorus using an endoscopic stapling device. The right gastric artery is divided at its origin using hemoclips. The lesser omentum and pars flaccida are divided at the border of the liver.

Division of the left gastric artery and vein is described at this point, with perfusion of the stomach via the short gastric arteries. Division of the left gastric artery facilitates laparoscopic dissection lymph nodes along the celiac axis. Division of the left gastric artery is not routinely performed for distal gastrectomy in Western centers.

Step 4: division of stomach and reconstruction The stomach is divided using an endoscopic stapler or alternatively via a standard gastrointestinal stapler via a minilaparotomy. Laparoscopic Billroth II anastomosis is performed with an endoscopic stapler, using laparoscopic suture techniques to close the gastrotomy and enterotomy for this anastomosis.

LAPAROSCOPIC WEDGE RESECTION

Laparoscopic wedge resection may be appropriate for small lesions that are potentially benign or for malignant lesions for which extensive surgical margins are not required

(e.g., GISTs [see Figure 15]). The lesion is visualized intraoperatively by means of endoscopy or marked preoperatively with India ink. Laparoscopic sutures are placed in the tissue surrounding the lesion and then retracted upward so that the portion of the gastric wall containing the lesion is elevated. A wedge resection is then performed with an endoscopic stapler. Intraoperative assessment of the surgical margin by a pathologist is useful to ensure that the margin is negative.

Procedures for Duodenal Cancer

LOCAL RESECTION OF DUODENAL TUMORS

Small duodenal tumors (e.g., polyps, villous adenomas, small GISTs, and neuroendocrine tumors) are occasionally amenable to local surgical resection. The diagnosis must be confirmed by endoscopic biopsy before resection. Endoscopy is also useful for localization of the lesion with respect to the ampulla and pancreatic head. Lateral lesions are removed by local resection far more easily than lesions on the medial wall are.

Operative Planning

Endoscopic confirmation of the diagnosis and localization of the lesion are crucial for operative planning. In addition, appropriate patient selection is essential. Local resection may be inappropriate for lesions close to the ampulla of Vater, for large duodenal lesions, for carcinomas, or for lesions on the medial aspect of the duodenum abutting the pancreas. For lesions in the second or third portion of the duodenum that are not amenable to local excision, pancreaticoduodenectomy may be required. Exposure may be achieved through an upper midline or right upper quadrant incision.

Figure 15 Laparoscopic resection of gastrointestinal stromal tumor. The tumor is visualized preoperatively and marked with India ink; alternatively, the tumor may be identified intraoperatively by means of endoscopy and its location marked with a suture. Traction sutures may be employed to “tent up” the lesion, thereby isolating it from the remainder of the stomach. The tumor is then resected with several firings of an endoscopic linear stapler. For lesions higher along the greater curvature near the cardia, wedge resection should be performed with an esophageal bougie in place to prevent inadvertent narrowing of the esophagogastric junction.

Operative Technique

The duodenum is mobilized with an extensive Kocher maneuver. The tumor is palpated and approached via a longitudinal duodenotomy. The tumor is grasped and everted, and a full-thickness portion of the duodenal wall is resected with the mass. Stay sutures are placed at the ends of the duodenotomy, and the duodenotomy is closed transversely, either with a TA stapler or with sutures. If a transverse closure would place too much tension on the suture line, a longitudinal closure is undertaken. If possible, omentum is placed over the duodenal closure.

Troubleshooting

Intraoperative endoscopy may be required to locate small duodenal lesions that cannot be palpated. During dissection, the location of the ampulla can be determined by passing a Fogarty catheter into the cystic duct, down the CBD, and through the ampulla. This measure requires that a cholecystectomy be done.

RESECTION OF DISTAL DUODENAL TUMORS

Lesions of the distal duodenum (e.g., GISTs, carcinoids, and, rarely, adenocarcinomas) are occasionally amenable to sleeve resection. Preoperative CT and endoscopy are essential to the workup of such lesions. Endoscopic biopsy should be performed if it is technically feasible.

Operative Technique

Step 1: exposure of duodenum Operative access to the distal duodenum is limited by the presence of the superior mesenteric vessels and the transverse mesocolon. The third and fourth portions of the duodenum may be approached either by moving the duodenum under the mesenteric vessels or by temporarily mobilizing the mesenteric vessels. In the first approach, the distal duodenum and the proximal jejunum are mobilized upward by dissecting the ligament of Treitz away from its mesenteric attachments. The proximal jejunum is divided with a stapler. After extensive mobilization, the duodenum is passed under the superior mesenteric vein and artery and moved to the right side of the abdomen.

In the second approach, the superior mesenteric vessels are mobilized upward to expose the third portion of the duodenum. The right colon is mobilized cephalad by incising the peritoneum along the white line of Toldt from the hepatic flexure to the cecum [see Figure 16a]. Division of the peritoneum is then continued along the cecum and medially to liberate the terminal ileum. The avascular attachments between the small bowel mesentery and the retroperitoneum are divided by means of cauterization and gentle blunt dissection [see Figure 16b].

Step 2: resection and anastomosis The duodenum is divided with the stapler approximately 1 cm proximal to

Figure 16 Local resection of duodenal tumors. Mobilization of the right colon and upward retraction of the small bowel mesentery allow direct access to the third and fourth portions of the duodenum. Sleeve resection of the duodenum with subsequent duodenojejunostomy can then be performed. (a) Avascular peritoneal attachments of the right colon are divided, as well as avascular attachments underneath the small bowel mesentery. Dotted lines enclose the area of mesentery to be elevated from posterior attachments. (b) Cephalad retraction of the right colon, the small bowel, and the mesenteric vessels allows exposure of the third and fourth portions of the duodenum.

the tumor. If pancreatic invasion is identified, pancreaticoduodenectomy should be considered. The distal bowel is brought through the transverse mesocolon, and a side-to-side duodenojejunostomy is created with an outer layer of 3-0 silk and an inner layer of 3-0 polyglactin. Alternatively, the anastomosis may be performed to the second portion of the duodenum.

Troubleshooting

The blood supply to the third portion of the duodenum arises from numerous branches of the inferior pancreaticoduodenal arcade, each of which must be meticulously dissected, divided, and ligated to prevent pancreatic trauma. The distal duodenum receives its blood supply from branches of the superior mesenteric artery.

a

b

The duodenum should not be simply closed distally and drained via a gastrojejunostomy; if this is done, the proximal duodenum will not be properly decompressed.

Complications

Delayed gastric emptying is common with duodenojejunostomy; it generally responds to prolonged conservative therapy. A delay in the return of bowel function should generally be treated with nasogastric suction; on occasion, a percutaneous gastrostomy is required for proximal decompression. Postoperative pancreatitis may occur secondary to operative trauma; conservative management is usually sufficient.

AMPULLECTOMY

Local periampullary resection is indicated primarily for rare benign lesions, small neuroendocrine tumors of the pancreas, and small adenomatous or villous polyps. The likelihood of occult malignancy in an adenomatous periampullary tumor is significantly higher when the lesion is larger than 2 cm; caution is therefore indicated in attempting local resection of lesions of this size. The recurrence rate is high after local resection of any periampullary adenocarcinoma. The preoperative workup should include endoscopy with biopsy, EUS or transabdominal ultrasonography, CT scanning, and endoscopic retrograde cholangiopancreatography.

Operative Technique

The ampulla of Vater is resected together with the distal CBD and the distal pancreatic duct [see Figure 17]. A Kocher maneuver is performed, and a longitudinal duodenotomy is made to expose the ampulla. Identification of the ampulla may be facilitated by placing a Fogarty catheter in the CBD via the cystic duct after a cholecystectomy. If the ampulla is identified during exploration, it may simply be cannulated. Circumferential stay

c

Figure 17 Ampullectomy. (a) After a longitudinal duodenotomy is made, the common bile duct (CBD) is cannulated. Circumferential stay sutures of 4-0 polydioxanone are placed in the duodenal mucosa. A 2 cm periampullary tumor is visualized. (b) The ampullary tumor is removed from the underlying duodenum with the electrocautery. The CBD and the pancreatic duct are entered and separately cannulated. The CBD is typically seen at the 11 o'clock position, and the pancreatic duct is typically encountered at the 3 o'clock position. (c) The duodenal mucosa is sutured directly to the CBD and the pancreatic duct with 4-0 polydioxanone. In addition, the CBD and pancreatic duct are carefully connected with 4-0 polydioxanone sutures.

sutures are placed in the mucosa. The CBD is entered at approximately the 11 o'clock position, and duodenal mucosa is reattached to the duct with 4-0 polydioxanone sutures. The pancreatic duct is encountered at approximately the 3 o'clock position; it may be cannulated separately to facilitate identification. The pancreatic duct is approximated to the CBD, and the inferior pancreatic duct is sewn to the duodenal wall. The duodenum is closed transversely in two layers.

Troubleshooting

Frozen-section analysis may identify invasive adenocarcinoma, which is an indication for pancreaticoduodenectomy. This possibility should be carefully considered before the operation.

Financial Disclosures: None Reported.

and Dennis R. Klassen, MD, FRCS(C), FACS*

Cholecystectomy is the treatment of choice for symptomatic gallstones because it removes the organ that contributes to both the formation of gallstones and the complications ensuing from them.¹ The morbidity associated with cholecystectomy is attributable to injury to the abdominal wall in the process of gaining access to the gallbladder (i.e., the incision in the abdominal wall and its closure) or to inadvertent injury to surrounding structures during dissection of the gallbladder. Efforts to diminish the morbidity of open cholecystectomy have led to the development of laparoscopic cholecystectomy, made possible by modern optics and video technology.

Carl Langenbuch performed the first cholecystectomy in Berlin, Germany, in 1882. Erich Mühe performed the first laparoscopic cholecystectomy in Germany in 1985,² and by 1992, 90% of cholecystectomies in the United States were being performed laparoscopically. Compared with open cholecystectomy, the laparoscopic approach has dramatically reduced hospital stay, postoperative pain, and convalescent time. However, rapid adoption of laparoscopic cholecystectomy as the so-called gold standard for treatment of symptomatic gallstone disease was associated with complications, including an increased incidence of major bile duct injuries.

Since the early 1990s, considerable advances have been made in instrumentation and equipment, and a great deal of experience with laparoscopic cholecystectomy has been amassed worldwide. Of particular significance is the miniaturization of and improvement in optics and instruments, which have reduced the morbidity of the procedure by making possible ever-smaller incisions. With proper patient selection and preparation, laparoscopic cholecystectomy is being safely performed on an outpatient basis in many centers.³

The primary goal of cholecystectomy is removal of the gallbladder with minimal risk of injury to the bile ducts and surrounding structures. Our approach is designed to maximize the safety of both routine and complicated cholecystectomies. In what follows, we describe our approach and discuss current indications and techniques for imaging and exploring the common bile duct (CBD).

Laparoscopic Cholecystectomy

PREOPERATIVE EVALUATION

To plan the surgical procedure, assess the likelihood of conversion to open cholecystectomy, and determine which patients are at high risk for CBD stones, the surgeon must

obtain certain data preoperatively. Useful information can be obtained from the patient's history, imaging studies, and laboratory tests.

Preoperative Data

History and physical examination A good medical history provides information about associated medical problems that may affect the patient's tolerance of pneumoperitoneum. Patients with cardiorespiratory disease may have difficulty with the effects of CO₂ pneumoperitoneum on cardiac output, lung inflation pressure, acid-base balance, and the ability of the lungs to eliminate CO₂. Most bleeding disorders can also be identified through the history. A disease-specific history is important in identifying patients in whom previous episodes of acute cholecystitis may make laparoscopic cholecystectomy more difficult, as well as those at increased risk for choledocholithiasis (e.g., those who have had jaundice, pancreatitis, or cholangitis).⁴⁻⁹

Physical examination identifies patients whose body habitus is likely to make laparoscopic cholecystectomy difficult and is helpful for determining optimal trocar placement. Abdominal examination also reveals any scars, stomas, or hernias that are likely to necessitate the use of special techniques for trocar insertion.

Imaging studies Ultrasonography is highly operator dependent, but in capable hands, it can provide very useful information. It is the best test for diagnosing cholelithiasis, and it can usually determine the size and number of stones.⁴ Large stones indicate that a larger incision in the skin and the fascia will be necessary to retrieve the gallbladder. Multiple small stones suggest that the patient is more likely to require operative cholangiography (if a policy of selective cholangiography is practiced) [see Operative Technique, Step 5, below]. A shrunken gallbladder, a thickened gallbladder wall, and pericholecystic fluid on ultrasonographic examination are significant predictors of conversion to open cholecystectomy. The presence of a dilated CBD or CBD stones preoperatively is predictive of choledocholithiasis. Other intra-abdominal pathologic conditions, either related to or separate from the hepaticobiliary-pancreatic system, may influence operative planning.

Preoperative imaging studies of the CBD may allow the surgeon to identify patients with CBD stones before surgery. Such imaging may involve endoscopic retrograde cholangiopancreatography (ERCP) [see 5:18 *Gastrointestinal Endoscopy*],¹⁰ magnetic resonance cholangiopancreatography

(MRCP) [see Figure 1],^{11,12} or endoscopic ultrasonography (EUS). These imaging modalities also provide an anatomic map of the extrahepatic biliary tree, identifying unusual anatomy preoperatively and helping the surgeon plan a safe operation. Endoscopic sphincterotomy (ES) is performed during ERCP if stones are identified in the CBD. MRCP has an advantage over ERCP and EUS in that it is noninvasive and does not make use of injected iodinated contrast solutions.¹¹ Most surgeons would probably recommend that preoperative cholangiography be performed selectively in patients with clinical or biochemical features associated with a high risk of choledocholithiasis. The specific modality used in such a case varies with the technology and expertise available locally.

Laboratory tests Preoperative blood tests should include liver function, renal function, electrolyte, and coagulation studies. Abnormal liver function test results may reflect choledocholithiasis or primary hepatic dysfunction.

Figure 1 Laparoscopic cholecystectomy. (a) and (b) Preoperative magnetic resonance cholangiopancreatography alerts the surgeon to abnormal anatomy and the presence of stones in the distal common bile duct (CBD). Acc = accessory duct entering the common hepatic duct near the neck of the gallbladder; CHD = common hepatic duct; Duo = duodenum; GB = gallbladder, containing stones; LHD = left hepatic duct; PD = pancreatic duct; RHD = right hepatic duct.

Selection of Patients

Patients eligible for outpatient cholecystectomy

Patients in good general health who have a reasonable amount of support from family or friends and who do not live too far away from adequate medical facilities are eligible for outpatient cholecystectomy, especially if they are at low risk for conversion to laparotomy [see Special Considerations, Conversion to Laparotomy, below].³ These patients can generally be discharged home from the recovery room 6 to 12 hours after surgery provided that the operation went smoothly, their vital signs are stable, they are able to void, they can manage at least a liquid diet without vomiting, and their pain can be controlled with oral analgesics.

Technically challenging patients Before performing laparoscopic cholecystectomy, the surgeon can often predict which patients are likely to be technically challenging. These include patients who have a particularly unsuitable body habitus, those who are highly likely to have multiple and dense peritoneal adhesions, and those who are likely to have distorted anatomy in the region of the gallbladder.

Morbidly obese patients present specific difficulties [see Operative Technique, Step 1, Special Considerations in Obese Patients, below].¹³ Small, muscular patients have a noncompliant abdominal wall, resulting in a small working space in the abdomen and necessitating high inflation pressures to obtain reasonable exposure.

Patients with a history of multiple abdominal operations, especially in the upper abdomen, and those who have a history of peritonitis are likely to pose difficulties because of peritoneal adhesions.¹⁴ These adhesions make access to the abdomen more risky and exposure of the gallbladder more difficult. Patients who have undergone gastroduodenal surgery, those who have any history of acute cholecystitis, those who have a long history of recurrent gallbladder attacks, and those who have recently had severe pancreatitis are particularly difficult candidates for laparoscopic cholecystectomy. These patients may have dense adhesions in the region of the gallbladder, the anatomy may be distorted, the cystic duct may be foreshortened, and the CBD may be very closely and densely adherent to the gallbladder. Such patients are a challenge to the most experienced laparoscopic surgeon. When such problems are encountered, conversion to open cholecystectomy should be considered early in the operation.^{14,15}

Predictors of choledocholithiasis CBD stones may be discovered preoperatively, intraoperatively, or postoperatively. The surgeon's goal is to clear the ducts but to use the smallest number of procedures with the lowest risk of morbidity. Thus, before elective laparoscopic cholecystectomy, it is desirable to classify patients into one of three groups: high risk (those who have clinical jaundice or cholangitis, visible choledocholithiasis, or a dilated CBD on ultrasonography), moderate risk (those who have hyperbilirubinemia, elevated alkaline phosphatase levels, pancreatitis, or multiple small gallstones), and low risk.

In our institution, where MRCP and EUS are available and reliable and where ERCP achieves stone clearance rates higher than 90%, we recommend the following approach: (1) preoperative ERCP and sphincterotomy (if required) for high-risk patients and (2) MRCP, EUS, or intraoperative fluoroscopic cholangiography for moderate-risk patients. Patients at low risk for CBD stones do not routinely undergo cholangiography [see Figure 2]. Laparoscopic CBD exploration

and postoperative ERCP appear to be equally effective in clearing stones from the CBD.

Ultimately, surgeons and institutions must establish a reasonable approach to choledocholithiasis that takes into account the expertise and equipment locally available.

Contraindications There are few absolute contraindications to laparoscopic cholecystectomy. Certainly, no patient who poses an unacceptable risk for open cholecystectomy should be considered for laparoscopic cholecystectomy, because it is always possible that conversion will become necessary. Of the relative contraindications, surgical inexperience is the most important.

Neither ascites nor hernia is a contraindication to laparoscopic cholecystectomy. Ascites can be drained and the gallbladder visualized. Large hernias may present a problem, however, because with insufflation, the gas preferen-

tially fills the hernia. Patients with large inguinal hernias may require an external support to minimize this problem and the discomfort related to pneumoscrotum. Patients with umbilical hernias can have their hernias repaired while they are undergoing laparoscopic cholecystectomy. For such patients, the initial trocar should be placed by open insertion according to the Hasson technique [see Operative Technique, Step 1, *below*], with care taken to avoid injury to the contents of the hernia. The sutures required to close the hernia defect can be placed before insertion of the initial trocar. For patients with small incisional hernias, laparoscopic cholecystectomy can proceed as usual. The hernia may be repaired at the same operation if the cholecystectomy goes smoothly and there is no peritoneal contamination. For large incisional hernias, we would proceed with laparoscopic cholecystectomy, limiting adhesiolysis to that

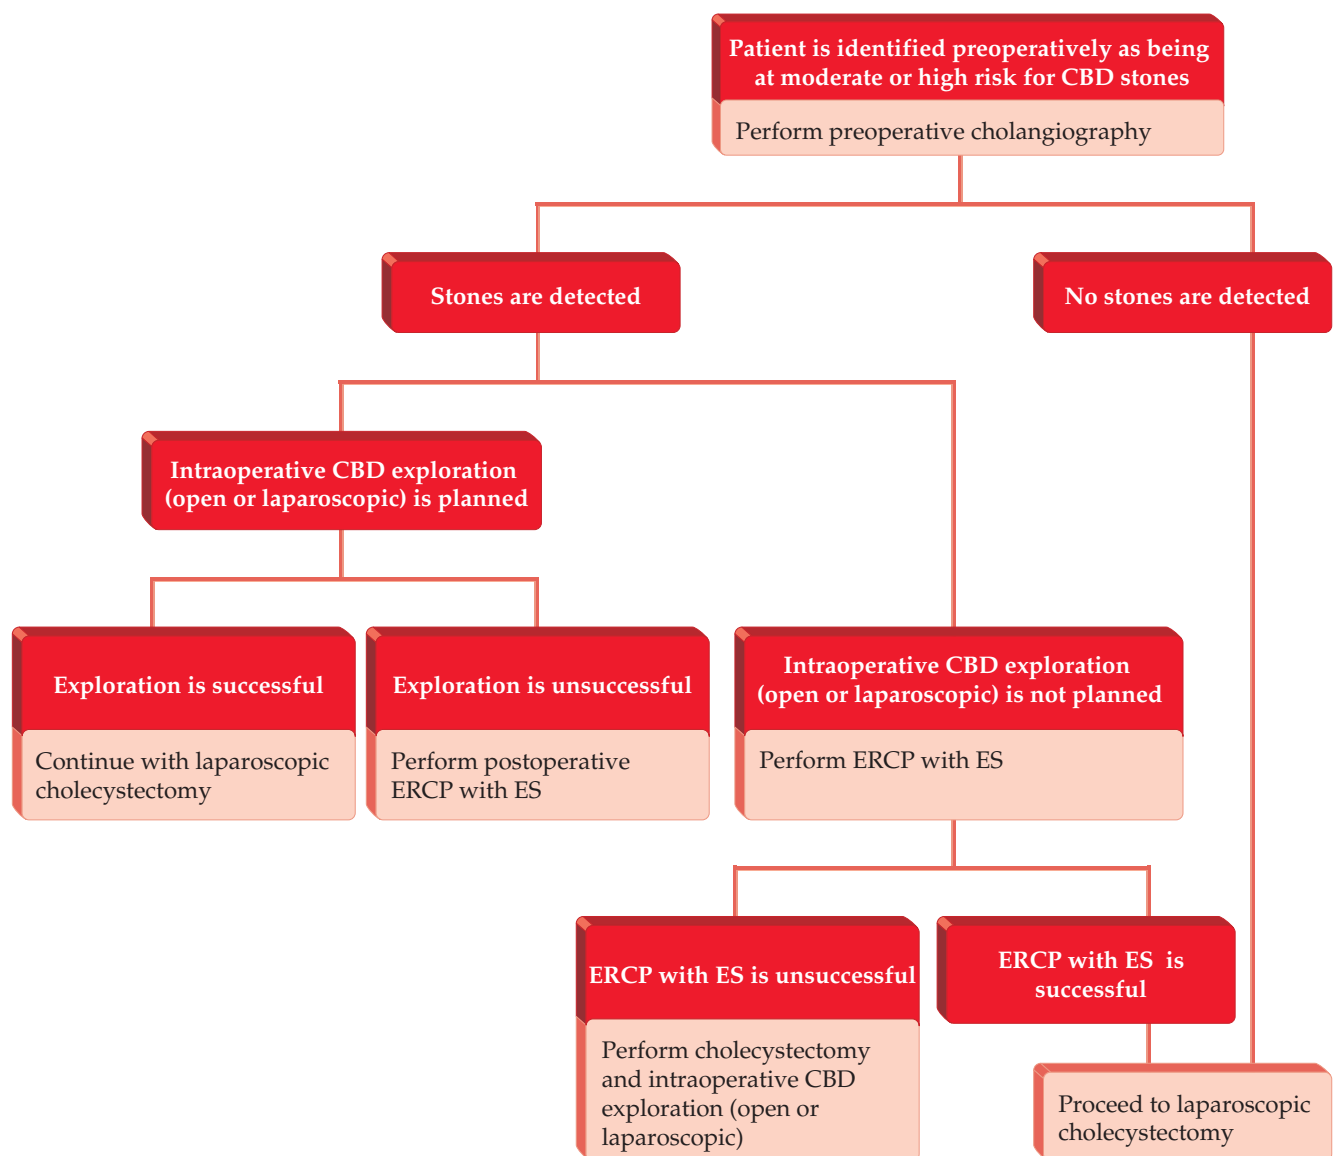

Figure 2 Laparoscopic cholecystectomy. Shown is an algorithm outlining the use of preoperative cholangiography in patients at moderate or high risk for common bile duct (CBD) stones. ERCP = endoscopic retrograde cholangiopancreatography; ES = endoscopic sphincterotomy.

required to safely perform the procedure. Patients with stomas may also undergo laparoscopic cholecystectomy provided that the appropriate steps are taken to prevent injury to the bowel during placement of trocars and division of adhesions.

Patients with cirrhosis or portal hypertension are at high risk for morbidity and mortality with open cholecystectomy.^{16,17} If absolutely necessary, laparoscopic cholecystectomy may be attempted by an experienced surgeon. The risk of bleeding can be minimized by rigorous preoperative preparation, meticulous dissection with the help of magnification available through the laparoscope, and use of electrocautery and enabling hemostatic devices.

Patients with bleeding diatheses, such as hemophilia, von Willebrand disease, and thrombocytopenia, may undergo laparoscopic cholecystectomy. They require appropriate preoperative and postoperative care and monitoring, and a hematologist should be consulted.

Questions have been raised about whether laparoscopic cholecystectomy should be performed in pregnant patients; it has been argued that the increased intra-abdominal pressure may pose a risk to the fetus. Because of the enlarged uterus, open insertion of the initial trocar is mandatory, and the positioning of other trocars may have to be modified according to the position of the uterus. Inflation pressures should be kept as low as possible, and prophylaxis of deep vein thrombosis (DVT) is recommended. Despite these potential problems, safe performance of laparoscopic cholecystectomy and other laparoscopic procedures in pregnant patients is increasingly being described in the literature. If cholecystectomy is necessary before delivery, the second trimester is the best time for it.^{18–21}

Patients in whom preoperative imaging gives rise to a strong suspicion of gallbladder cancer should probably undergo open surgical management.

OPERATIVE PLANNING

Antibiotic Prophylaxis

Some surgeons recommend routine preoperative administration of antibiotics to all patients undergoing cholecystectomy, on the grounds that inadvertent entry into the gallbladder is not uncommon and can lead to spillage of bile or stones into the peritoneal cavity. Other surgeons do not recommend routine prophylaxis. Resolution of this controversy awaits appropriate prospective trials. We recommend selective use of antibiotic prophylaxis for patients at highest risk for bacteria in the bile (including those with acute cholecystitis or CBD stones, those who have previously undergone instrumentation of the biliary tree, and those older than 70 years) and for patients with prosthetic heart valves and joint prostheses.

Prophylaxis of DVT

The reverse Trendelenburg position used during laparoscopic cholecystectomy, coupled with the positive intra-abdominal pressure generated by CO₂ pneumoperitoneum and the vasodilatation induced by general anesthesia, leads to venous pooling in the lower extremities. This consequence may be minimized by using antiembolic stockings or by wrapping the legs with elastic bandages. Subcutaneous heparin and pneumatic compression devices may be employed

for patients at increased risk for DVT [see 6:6 *Venous Thromboembolism*]. As yet, however, there is no convincing evidence that the incidence of DVT is higher with laparoscopy than with open surgery.

Patient Positioning

Typically, the patient is positioned supine and the surgeon stands to the patient's left side [see Figure 3].

The camera operator usually stands on the patient's left and to the left of the surgeon, while the assistant stands on the patient's right. The video monitor is positioned on the patient's right above the level of the costal margin. If a second monitor is available, it should be positioned on the patient's left to the right of the surgeon, where the assistant can have an unobstructed and comfortable view. Exposure can be improved by tilting the patient in the reverse Trendelenburg position and rotating the table with the patient's right side up. Gravity pulls the duodenum, colon, and omentum away from the gallbladder, thereby increasing the working space available in the upper abdomen.

The operating room (OR) table should allow easy access for a fluoroscopic C arm to facilitate intraoperative cholangiography. The table cover should be radiolucent.

Equipment

The equipment required for laparoscopic cholecystectomy includes an optical system, an electronic insufflator, trocars (cannulas), surgical instruments, and hemostatic devices [see Table 1].

Optical system The laparoscope can provide either a straight, end-on (0°) view or an angled (30° or 45°) view. Scopes that provide an end-on view are easier to learn to use,

Figure 3 Laparoscopic cholecystectomy. A patient undergoing laparoscopic cholecystectomy should be positioned so as to allow easy access to the gallbladder and a clear view of the monitors. Shown are the positions of the surgeon, the camera operator, and the assistant in the operating room.

but angled scopes are more versatile. Scopes with a 30° angle cause less disorientation than those with a 45° angle and are ideal for laparoscopic cholecystectomy. Excellent 30° scopes are currently available in diameters of 10, 5, and 3.5 mm.

Fully digital flat-panel displays are now available that yield better resolution than analog video monitors, take up less

space, are less subject to signal interference, and require less power. The introduction of high-definition optics has further improved the quality of the image. The associated 16:9 display increases the width of the field of view.

The resolution and quality of the final image depend on (1) the brightness of the light source; (2) the integrity of the

Table 1 Equipment for Laparoscopic Cholecystectomy

Instrument/Device	Number	Size	Comments
Laparoscopic cart High-intensity halogen light source (150–300 watts) High-flow electronic insufflator (minimum flow rate of 106 L/min) Laparoscopic camera box Videocassette digital video and still image recorder (optional) Digital still image capture system (optional)			
Laparoscope	1	3.5–10 mm	Available in 0° and angled views; we prefer to use a 30° 5 mm diameter laparoscope
Atraumatic grasping forceps	2–4	2–10 mm	Selection of graspers should allow surgeon choice appropriate to thickness and consistency of gallbladder wall; insulation is unnecessary
Large-tooth grasping forceps	1	10 mm	Used to extract gallbladder at end of procedure
Curved dissector	1	2–5 mm	Should have a rotatable shaft; insulation is required
Scissors	2–3	2–5 mm	One curved and one straight scissors with rotating shaft and insulation; additional microscissors may be helpful for incising cystic duct
Clip appliers	1–2	5–10 mm	Either disposable multiple clip applier or 2 manually loaded reusable single clip appliers for small and medium-to-large clips; 5 and 10 mm diameter
Dissecting electrocautery hook or spatula	1	5 mm	Available in various shapes according to surgeon's preference; instrument should have channel for suction and irrigation controlled by trumpet valve(s); insulation required
High-frequency electrical cord	1		Cord should be designed with appropriate connectors for electrosurgical unit and instruments being used
Suction-irrigation probe	1	5–10 mm	Probe should have trumpet valve controls for suction and irrigation; may be used with pump for hydrodissection
10-to-5 mm reducers	2		Allow use of 5 mm instruments in 10 mm trocar without loss of pneumoperitoneum; these are often unnecessary with newer disposable trocars and may be built into some reusable trocars
5-to-3 mm reducer	1		Allows use of 2–3 mm instruments and ligating loops in 5 mm trocars
Ligating loops			
Endoscopic needle holders	1–2	5 mm	
Cholangiogram clamp with catheter	1	5 mm	Allow passage of catheter and clamping of catheter in cystic duct
Veress needle	1		Used if initial trocar is inserted by percutaneous technique
Allis or Babcock forceps	1–2	5 mm	Allow atraumatic grasping of bowel or gallbladder
Long spinal needle	1	14 gauge	Useful for aspirating gallbladder percutaneously in cases of acute cholecystitis or hydrops
Retrieval bag	1		Useful for preventing spillage of bile or stones in removal of inflamed or friable gallbladder; facilitates retrieval of spilled stones

fiberoptic cord used to convey the light; (3) clean and secure connections between the light source and the scope; (4) the quality of the laparoscope, the camera, and the monitor; and (5) correct wiring of the components. The distal end of the scope must be kept clean and free of condensation: bile, blood, or fat will reduce brightness and distort the image. Lens fogging can be prevented by immersion in heated water or by antifogging solutions.

Insufflator CO₂ is the preferred insufflating gas for laparoscopic procedures because it is highly soluble in water and does not support combustion when electrocautery is used. The CO₂ should be insufflated with an electronic pump capable of a flow rate of at least 10 L/min; most current systems have a maximum flow rate of 20 L/min or higher. The insufflator is connected to one of the trocars by means of a flexible tube and a stopcock.

Trocars For cholecystectomy, at least one trocar site must be large enough to allow passage of the gallbladder and any stones removed. Most surgeons prefer to use a 10/12 mm trocar at the umbilicus for this purpose. The other trocars can range from 2 to 12 mm, depending on the size of the instruments to be placed through them. The conventional approach is to use a 10/12 mm trocar at the operating port site and 5 mm trocars for the other instruments; however, if a 5 mm laparoscope and a 5 mm clip applier are used, the operating port size can be reduced to 5 mm. Although 2 mm instrumentation is also available, it must be remembered that, as a rule, the smaller the working port, the less versatile the instruments. In our experience, the combination of a 10 mm umbilical trocar, a 5 mm operating port, and 2 mm ports for grasping forceps is a good one: optical quality is maintained, little flexibility is lost with respect to selecting operating instruments, trocar size is minimized, and the cosmetic result is excellent.

Hemostatic devices Hemostasis can be achieved with monopolar or bipolar electrocauterization. A monopolar electrocautery can be connected to most available instruments; however, bipolar electrocauterization may eventually prove safer. With a monopolar electrocautery, depth of burn is less predictable, current can be conducted through noninsulated instruments and trocars, and any area of the instrument that is stripped of insulation may conduct current and result in a burn. Caution is essential when the electrocautery is used near metallic hemostatic clips because delayed sloughing may occur.

Electrocauterization should be avoided near the CBD because delayed bile duct injuries and leaks may occur as a result of sloughing from a burned area and devascularization of the duct. Care must be exercised when cautery is employed near the bowel and when intra-abdominal adhesions are being taken down. The electrocautery can be used with a forceps, scissors, hooks (L or J shaped), a spatula, and other instruments. Some cautery probes incorporate nonstick surfaces to prevent buildup of eschar. The use of hand-activated cautery probes and the presence of a channel that allows suction and irrigation through the cautery probes are especially convenient.

More advanced energy sources and instruments are also available. Bipolar devices designed to weld tissues have proved capable of achieving superb hemostasis. Ultrasonic dissecting shears can also be used to dissect and coagulate tissues effectively and precisely. For laparoscopic cholecystectomy, however, such advanced—and costly—devices are rarely needed.

OPERATIVE TECHNIQUE

Step 1: Placement of Trocars and Accessory Ports

Placement of initial trocar The first step in laparoscopic cholecystectomy is the creation of pneumoperitoneum and the insertion of an initial trocar through which the laparoscope can be passed. This step is critical because complications resulting from improper placement may cause serious morbidity and death. The surgeon may use either a percutaneous technique or an open technique. We prefer the open technique, which eliminates the risks inherent in the blind puncture [see Figure 4].^{22,23}

Scars Patients who have previously undergone abdominal surgery may have adhesions, both to the undersurface of the abdominal wall and intra-abdominally. Adhesions to the undersurface of the abdominal wall make access to the abdominal cavity potentially hazardous, particularly when the percutaneous method is used for placement of the initial trocar. Scars from previous operations may affect insertion of the initial trocar, depending on its orientation and location. If a patient has a scar in the lower abdomen (e.g., from a Pfannenstiel incision or an incision in the right lower quadrant for an appendectomy), the position of the initial trocar need not be changed. If the scar is in the upper abdomen, the initial trocar may be inserted below the umbilicus in the midline. If there is a long midline scar that is impossible to avoid, careful dissection of the peritoneum through a vertical incision that is somewhat longer than usual affords safe access to the peritoneum in most cases.

An alternative is to insert the initial trocar high in the epigastrium or in the right anterior axillary line, where bowel adhesions are less common. The laparoscope is inserted through this trocar and used to examine the undersurface of the old scar for a clear site near the umbilicus, where a 10 mm trocar can be placed. Previous laparoscopy, which rarely creates significant intra-abdominal adhesions, rarely necessitates modification of trocar insertion.

The surgeon should also consider the reason for the previous surgery. For example, a patient who underwent an appendectomy for perforated appendicitis may have had diffuse peritonitis and may have adhesions well away from the old scar.

Placement of accessory ports In most cases, four ports are necessary. The first port is for the laparoscope; the remaining ports are for grasping forceps, dissectors, and clip appliers. The precise position of the accessory ports depends on the surgeon's preference, the patient's body habitus, and the presence or absence of previous scars or intra-abdominal adhesions [see Figure 5]. A rigid approach to port placement is inappropriate: trocar placement determines operative exposure, and improper placement will haunt the surgeon throughout the procedure. In some cases, a fifth trocar is required to elevate a floppy liver or to depress or retract the omentum or a bulky hepatic flexure of the colon [see Figure 5].

Most surgeons elect to place one of the grasping forceps on the fundus of the gallbladder through an accessory port placed approximately in the anterior axillary line below the level of the gallbladder. Because the level of the gallbladder varies from patient to patient, the placement of this accessory port should not be decided on until the gallbladder is visualized. If the gallbladder is low lying and the trocar is placed too high, the surgeon will have difficulty achieving the appropriate angle

Figure 4 Laparoscopic cholecystectomy. With the open insertion technique, the initial trocar is placed under direct vision. (a) The umbilical skin is elevated with a sharp towel clip. A curvilinear incision is made in the inferior umbilical fold. The skin flap is elevated, and the raphe leading from the dermis to the fascia is thereby exposed. (b) The fascia is grasped in the midline between forceps and elevated. The fascia and the underlying peritoneum are incised under direct vision. (c) A blunt instrument is placed into the peritoneum to ensure that the undersurface of the peritoneum is free of adhesions. The opening can be enlarged sufficiently to allow placement of a blunt 10/11 mm trocar.

of retraction. As a general rule, positioning the trocar in the anterior axillary line approximately halfway between the costal margin and the anterosuperior iliac spine provides the appropriate exposure. A 2 to 5 mm port usually suffices at this site

because its only likely function is to allow retraction of the gallbladder. In some cases of acute cholecystitis, however, a larger port may be preferable so that a larger grasper can be inserted and used to hold the gallbladder without tearing it.

Figure 5 Laparoscopic cholecystectomy. (a) and (b) are two popular options for trocar positioning and instrument placement.

A second accessory port (also 2 to 5 mm) allows the surgeon to grasp the gallbladder in the area of the Hartmann pouch for retraction. This port is usually positioned just beneath the right costal margin. Some surgeons prefer it to be approximately at the midclavicular line; others prefer it to be higher and more medial, just to the right of the falciform ligament.

The main operating port should be 5 or 10 mm in diameter so that clip appliers can be readily placed through it and the laparoscope can be moved to this port at the end of the procedure. The positioning of this port is determined by the surgeon's preference and, in particular, by the patient's body habitus. The optimum placement is at about the same horizontal level as the gallbladder or slightly higher so that during the operation, the laparoscope and the operating instrument form an angle of about 90°. Some surgeons prefer to place the operative port in the midline, to the right of the falciform ligament; others prefer to place it to the left of the falciform ligament, passing the trocar underneath the ligament and elevating it with the trocar.

Surgeons should be encouraged to use both hands when performing laparoscopic cholecystectomy. One hand should control the grasping forceps holding the Hartmann pouch so that the gallbladder can be moved to provide the best possible exposure. The other hand should control the dissecting instruments placed through the operating port.

Special considerations in obese patients Port placement in obese patients may be complicated by the thick abdominal wall, the large amount of intra-abdominal fat, or both. A thick abdominal wall makes it more difficult to rotate the trocar around the normal fulcrum point in the abdominal wall. Consequently, the trocar must be placed at the angle most likely to be used during the procedure. When a trocar is tunneled through the abdominal wall, more of the cannula

is within the abdominal wall than if the trocar had been placed perpendicularly; accordingly, the trocar is less mobile. If the trocars are not easily rotated, the instruments placed through them will be difficult to manipulate smoothly. Thus, in the patient with a very thick pannus, a standard-length trocar may be too short. Displacement of trocars can lead to insufflation into the abdominal wall and consequently to subcutaneous emphysema, which further thickens the abdominal wall and hinders exposure.

To prevent such problems, special extra-length trocars designed for morbidly obese patients have been developed. It may also be necessary to place the trocars closer to the area of the gallbladder to ensure that the operating instruments can reach the gallbladder. For example, the initial port may have to be placed above the umbilicus.

In obese patients, the bulky falciform ligament and the large omentum may adversely affect exposure. A 30° laparoscope may help the surgeon see over the omentum and the high-lying hepatic flexure of the colon. In some cases, it is useful to place a fifth port so that the surgeon can retract the hepatic flexure downward. Fat may envelop the cystic duct and artery and the portal structures, obscuring normal anatomic landmarks. When the electrocautery is used, the heat melts the fat and causes it to sizzle and spray onto the lens of the laparoscope, resulting in a blurry image. To prevent this, the camera operator should pull the scope slightly away from the operative field during electrocauterization and then advance the scope during dissection. This should also be done when an ultrasonic dissector is being used.

Given that obese patients are more difficult candidates for open cholecystectomy and have a higher complication rate with laparotomy, the advantages of laparoscopic cholecystectomy in these individuals justify the effort needed to overcome the technical problems.

Step 2: Exposure of the Gallbladder and Calot Triangle

Dissection of adhesions Adhesions must be dissected to provide an unimpeded view of the gallbladder through the laparoscope. Not all intra-abdominal adhesions must be taken down, just enough to allow entry of accessory trocars under direct vision and thus permit access to the gallbladder. This process is facilitated by pneumoperitoneum, which provides traction on adhesions to the abdominal wall, and by the magnification provided by the optical system, which allows identification of the avascular plane of attachment.

The most difficult problem is positioning the dissecting instruments so that they can reach the undersurface of the anterior abdominal wall. A rigid trocar inserted through the anterior abdominal wall cannot be rotated enough to allow scissors passed through this port to cut adhesions to the anterior abdominal wall. In such cases, one or two trocars should be placed laterally, near the anterior axillary or midaxillary line. Instruments passed through these ports can easily be angled parallel to the anterior abdominal wall, and the adhesions can then be dissected without difficulty.

Bowel adhesions should be taken down with endoscopic scissors at their insertion to the abdominal wall, where they are least vascular. Electrocauterization, which is generally unnecessary, should be avoided because of the risk of thermal injury to the bowel. Interloop adhesions, which rarely interfere with exposure of the gallbladder, need not be dissected. Frequently, adhesions to the gallbladder occur as a reaction to inflammatory attacks [see Figure 6]. They are usually relatively avascular. Dissection of these adhesions should begin at the fundus of the gallbladder and should then proceed down toward the neck of the gallbladder. The best way to take them down is to grasp the gallbladder with one grasping forceps at the site where the adhesions attach and gradually place traction on the adhesions with the other hand. Usually, the adhesions peel down in an avascular plane. Dissection should continue until all adhesions to the inferolateral aspect of the gallbladder have been taken down. It is not necessary to divide adhesions between the superior surface of the liver and the undersurface of the diaphragm unless they impede superior retraction of the liver.

Exposing the Calot triangle Obtaining adequate exposure of the Calot triangle is a key step. First, the patient is placed in a reverse Trendelenburg position, with the table rotated toward the left side. Next, the fundus of the gallbladder and the right lobe of the liver are elevated toward the patient's right shoulder. One grasping forceps, inserted through the most lateral right-side port and held by an assistant, is placed on the fundus of the gallbladder [see Figure 7], and the gallbladder is retracted superiorly and laterally above the right hepatic lobe. This maneuver straightens out folds in the body of the gallbladder and permits initial visualization of the area of the Calot triangle. If the Calot triangle is still obscured, the patient can be placed in a steeper reverse Trendelenburg position, and the stomach can be emptied of air via an orogastric tube inserted by the anesthetist, or, if necessary, a fifth trocar can be inserted on the patient's right side to push down the duodenum.

In some patients, such as those with acute cholecystitis and hydrops of the gallbladder, the gallbladder is tense and distended, making it difficult to grasp and easy to tear. In these

Figure 6 Laparoscopic cholecystectomy. Adhesions of the duodenum and omentum to the gallbladder wall obscure the view of structures of the Calot triangle.

Figure 7 Laparoscopic cholecystectomy. Initial view of the gallbladder and related structures is facilitated by appropriate tilting of the operating table. The Hartmann pouch (HP), cystic duct (CD), and common bile duct (CBD) can be readily identified before any dissection.

patients, retraction of the fundus is difficult, and exposure of the Calot triangle is unsatisfactory. This problem is best managed by aspirating the contents of the gallbladder either percutaneously with a 14- or 16-gauge needle inserted into the fundus of the gallbladder under laparoscopic vision or by using the 5 mm trocar in the right upper abdomen to puncture the fundus and then aspirate with the suction irrigator. After the needle is withdrawn, a large atraumatic grasping forceps can be used to hold the gallbladder and occlude the hole; a 10 mm forceps may be preferred if the wall is markedly thickened. An alternative is to place a stitch or a ligating loop around the fundus of the collapsed gallbladder; the tail of the suture can then be grasped with a forceps to achieve a secure grip and prevent further leakage of gallbladder contents from the needle hole.

Once the fundus of the gallbladder is retracted superiorly by the assistant, the surgeon places a grasping forceps in the area of the Hartmann pouch. Using both hands, the surgeon controls the grasper on the Hartmann pouch and the operating instrument. The surgeon maneuvers the Hartmann pouch to provide various angles for safe dissection of the Calot triangle. Initially, lateral and inferior traction are placed on the Hartmann pouch, opening up the angle between the cystic duct and the common ducts [see Figure 8], avoiding their alignment [see Figure 9].

A large stone impacted in the gallbladder neck may impede the surgeon's ability to place the forceps on the Hartmann pouch. This problem can usually be managed by dislodging the stone early in the operation, as follows: the gallbladder is grasped as low as possible with one grasping forceps; a widely opening dissecting instrument, such as a right-angle dissector, a Babcock

forceps, or a curved dissector, is used to dislodge the stone and milk it up toward the fundus; with the same forceps or another large grasper, the stone is held up and away from the neck of the gallbladder, and appropriate retraction is provided.

If the stone cannot be disimpacted, an instrument can be used to elevate the infundibulum of the gallbladder superiorly, allowing exposure of the Calot triangle. Alternatively, one can attempt to crush the stone, but small pieces of the stone may fall into the cystic duct. A third option is to place a stitch in the Hartmann pouch and grasp the end of the stitch to provide exposure.

Step 3: Stripping of the Peritoneum

The key to avoiding injury to the major ducts during laparoscopic cholecystectomy is accurate identification of the junction between the gallbladder and the cystic duct [see Figure 10]. Unless the gallbladder–cystic duct junction is immediately obvious on examination of the Calot triangle anteriorly, our approach is to begin dissection of the Calot triangle posteriorly [see Figure 11]. From this approach, the insertion of the gallbladder neck into the cystic duct is usually more clearly identified, especially with the aid of a 30° laparoscope. Exposure is obtained by retracting the Hartmann pouch superomedially and is facilitated by looking from below with a 30° scope.

Dissection should always start high on the gallbladder and hug the gallbladder closely until the anatomy is identified clearly. Using a curved dissector, the surgeon gently teases away peritoneum attaching the neck of the gallbladder to the liver posterolaterally to visualize the funneling of the neck of the gallbladder into the cystic duct [see Figure 12]. Only the posterior layer of peritoneum is dissected; care must be taken not to dissect deeply in this area because of the risk of injury to the cystic artery [see Figure 13].

In some problem cases, edema, fibrosis, and adhesions make identification of the gallbladder–cystic duct junction very difficult. An anatomic landmark on the liver known as the Rouvier sulcus may be helpful in such circumstances [see Figure 11]. This sulcus, or the remnant of it, is present in

Figure 8 Laparoscopic cholecystectomy. The area of the Hartmann pouch is retracted laterally. The cystic duct (CD) is seen at an angle to the common hepatic duct (CHD) and the common bile duct (CBD).

Figure 9 Laparoscopic cholecystectomy. In this case, the gallbladder is retracted cephalad. The cystic duct (CD) can be seen running in the same direction as the common bile duct (CBD). The CBD may be misinterpreted as being the cystic duct and consequently is at risk for injury.

Figure 10 Laparoscopic cholecystectomy. The gallbladder–cystic duct (GB-CD) junction is clearly seen. This should be dissected circumferentially, allowing a 360° view.

Figure 11 Laparoscopic cholecystectomy. A view from below with a 30° laparoscope demonstrates the point for beginning dissection (arrow), where the gallbladder funnels down to its junction with the cystic duct. Just below this point can be seen a cleft in the liver known as the Rouvier sulcus. This cleft, present in 70 to 80% of livers, reliably indicates the plane of the common bile duct.

Figure 12 Laparoscopic cholecystectomy. The peritoneum is dissected from the gallbladder–cystic duct junction (arrow), as seen from below through a 30° angled laparoscope.

70 to 80% of livers and usually contains the right portal triad or its branches. Its location is consistently to the right of the hepatic hilum and anterior to the caudate process (Couinaud segment 1). This landmark reliably indicates the plane of the CBD. Therefore, dissection dorsal to it should be done with caution. Once the funneling of the gallbladder into the cystic duct has been identified, the area of the Hartmann pouch should be again pulled laterally and inferiorly so that the anterior peritoneum can be dissected while the 30° scope is angled to view the area. The two-handed technique facilitates

Figure 13 Laparoscopic cholecystectomy. Arterial bleeding can be seen (arrow) from a branch of the cystic artery injured during dissection from the posterior approach.

Figure 14 Laparoscopic cholecystectomy. The superior border of the cystic duct has been dissected. Funneling of the gallbladder into the cystic duct is clearly seen (arrow).

the surgeon's movement between the posterior and anterior aspects of the Calot triangle, providing complete visualization. Dissection should always take place at the gallbladder–cystic duct junction, staying close to the gallbladder to avoid inadvertent injury to the CBD. A curved dissecting forceps is used to strip the fibroareolar tissue just superior to the cystic duct. The superior border of the cystic duct can then be identified and the cystic duct gently and gradually dissected [see Figure 14]. The cystic duct lymph node is a useful landmark at this location and may facilitate identification of the gallbladder–cystic duct junction.

When traction is placed as described, the cystic artery tends to run parallel and somewhat cephalad to the cystic duct. This artery can often be identified by noting its close relation

to the cystic duct lymph node. Complete dissection of the area between the cystic duct and the artery develops a window through which the liver should be visible. The cystic duct is then encircled with a curved dissecting instrument or an L-shaped hook. Downward traction should be applied to the cystic duct to open this window and ensure that there is no ductal structure running through this space in the Calot triangle to join the cystic duct (i.e., the right hepatic duct).

Dissection of the Calot triangle should be completed before the cystic duct is clipped or divided. This is best accomplished by dissecting the neck of the gallbladder from the liver bed. Unequivocal identification of the gallbladder–cystic duct junction is imperative.^{24,25} The cystic duct should be dissected for a length sufficient to permit secure placement of two clips; it is not necessary, and indeed may be hazardous, to attempt to dissect the cystic duct–CBD junction.

The cystic artery is exposed next [see Figure 15]. A small vein can usually be identified in the space between the cystic duct and the cystic artery; it can usually be pulled up anteriorly and cauterized. Because dissection is done near the gallbladder, it is not unusual to encounter more than one branch of the cystic artery. Each of these branches should be dissected free of the fibroareolar tissue. Care should also be taken to ensure that the right hepatic artery is not inadvertently injured as a result of being mistaken for the cystic artery.

Step 4: Control and Division of the Cystic Duct and Cystic Artery

At this point, the cystic duct is clipped on the gallbladder side, and a cholangiogram is obtained if desired [see Step 5, below]. If a cholangiogram is not desired, three or four clips should be placed on the cystic duct and the cystic duct divided between them. Two or three hemostatic clips are placed on the cystic artery, and the vessel is divided. It is prudent to incise the artery partially before transecting it

completely to ensure that the clips are secure and that there is no pulsatile bleeding. Once the artery is completely divided, the proximal end will retract medially, making it more difficult to expose and control the artery safely if bleeding occurs. Electrocauterization should be avoided near the cystic duct and all metallic clips. Electric current will be conducted through metallic clips and may result in delayed sloughing of the duct or a clip. Delayed injuries to the CBD may be caused by a direct burn to the duct or by sparking from noninsulated instruments or clips during dissection. An alternative is to use locking polymer clips that fit through 5 mm ports, clip across a greater width of tissue, and do not conduct electricity.

Control of the short or wide cystic duct Edema and acute inflammation may lead to thickening and foreshortening of the cystic duct, with subsequent difficulties in dissection and ligation. If the duct is edematous, clips may cut through it; if the duct is too wide, the clip may not occlude it completely. A modified clipping technique can be employed, with placement of an initial clip to occlude as much of the duct as possible. The occluded portion of the duct is then incised, and a second clip is placed flush with the first so as to occlude the rest of the duct. Alternatively, wider polymer clips may be used.

Because this technique is not always possible, the surgeon should be familiar with techniques for ligating the duct with either intracorporeal or extracorporeal ties. It is extremely helpful to know how to tie extracorporeal ties so that the cystic duct can be ligated in continuity before it is divided. In some cases, the duct can be divided, held with a forceps, and controlled with a ligating loop. If there is concern about secure closure of the cystic duct, a closed suction drain may be placed. If inflammation, as in cholecystitis, has caused the duct to be shorter than usual, dissection must be kept close to the gallbladder to avoid inadvertent injury to the CBD. A short cystic duct is often associated with acute cholecystitis. Patient blunt dissection with the suction-irrigation device may be the safest technique.

Cystic duct stones Stones in the cystic duct may be visualized or felt during laparoscopic cholecystectomy. Every effort should be made to milk them into the gallbladder before applying clips. Placing a clip across a stone may push a fragment of the stone into the CBD and will increase the risk that the clip will become displaced, leading to a bile leak. If the stone cannot be milked into the gallbladder, a small incision can be made in the cystic duct (as is done for cholangiography), and the stone can often be expressed and retrieved. Given that cystic duct stones are predictive of CBD stones, cholangiography or intraoperative ultrasonography is indicated.²⁶

Step 5: Intraoperative Cholangiography

Whether intraoperative cholangiography should be performed routinely is still controversial. Advocates believe that this technique enhances understanding of the biliary anatomy, thus reducing the risk of bile duct injury^{27,28}; at present, however, there are no objective data to confirm this impression. Cholangiography is not a substitute for meticulous dissection, and injuries to the CBD can occur before cystic duct dissection reaches the point at which cholangiography can be performed. Catheter-induced injuries and perforations of the biliary tree have been reported, and cholangiograms have been misinterpreted. On the other hand, one of the main advantages of cholangiography is that injuries can be

Figure 15 Laparoscopic cholecystectomy. Dissection of the Calot triangle further exposes the cystic duct (CD) and the cystic artery (CA) near their entry into the gallbladder (GB) in preparation for clipping and division.

recognized during the operation and promptly repaired. Another advantage of routine cholangiography is that it helps develop the skills required for more complex biliary tract procedures, such as transcystic CBD exploration.

The two methods of laparoscopic cholangiography differ in their technique for introducing the cholangiogram catheter into the cystic duct. In both approaches, a clip is placed at the gallbladder–cystic duct junction and a small incision is made in the anterior wall of the cystic duct. In the first technique, a specially designed 5 mm cholangiogram clamp (the Olsen clamp) with a 5 French catheter is inserted via a subcostal trocar. For easy guidance of the catheter into the incision in the cystic duct, the catheter should be parallel, rather than perpendicular, to the cystic duct. This angle is facilitated by placing the subcostal port directly below the costal margin, near the anterior axillary line. A fifth trocar may occasionally be needed if exposure is lost when one of the grasping forceps is removed to allow passage of the cholangiogram clamp. The clamp and the catheter are then brought to the cystic duct under direct vision, and the catheter is steered into the duct [see Figure 16]. The clamp is then closed, holding the catheter in position and sealing the duct to avoid extravasation of dye.

In the second method, the cholangiogram catheter is introduced percutaneously through a 12- to 14-gauge catheter, inserted subcostally as described (see above). The surgeon then grasps the cholangiogram catheter and directs it into the cystic duct. A hemostatic clip is applied to secure the catheter in place. If passage of the catheter into the cystic duct is prevented by the Heister valve, a guide wire can be passed initially.

If the cystic duct is tiny and cannulation is expected to be difficult or impossible, the gallbladder can be punctured, bile aspirated, and contrast material injected through the gallbladder until the biliary tree is filled.

Figure 16 Laparoscopic cholecystectomy. The cystic duct has been clipped, a small incision has been made for placement of the cholangiogram catheter, and the catheter has been advanced through the specialized cholangiogram clamp into the cystic duct.

The cannulas and operating instruments should be positioned so as not to obstruct the view of the biliary tree. If the cannulas cannot be positioned outside the x-ray window, radiolucent cannulas should be used, or the cannulas should be removed and replaced after the cholangiogram. A cholangiogram that does not visualize the biliary tree from the liver to the duodenum is inadequate.

Fluoroscopic cholangiography [see Figure 17] may be performed either with hard-copy film or with digital imaging and storage. After the C arm is positioned, with the operating staff protected behind a lead screen, full-strength contrast is slowly injected under fluoroscopic control. The goal is to visualize the biliary tree in its entirety, including the right and left hepatic ductal systems as well as the distal duct. Once the cholangiogram is obtained, the catheter is removed, and the cystic duct is double-clipped and transected.

Laparoscopic ultrasonography Evaluation of the biliary tree with intraoperative laparoscopic ultrasonography appears to be as accurate as intraoperative fluorocholangiography in identifying biliary stones.^{28,29} This modality has several advantages over conventional cholangiography: it does not expose patients and staff to radiation; contrast agents are unnecessary; there is no need to cannulate the cystic duct; significantly less time is required; the capital cost of most ultrasound units is less than that of fluoroscopic equipment; and disposable cholangiogram catheters are not needed.

Most of the laparoscopic ultrasound devices in use at present are 7.5 MHz linear-array rigid probes 10 mm in diameter. Flexible probes capable of multiple frequencies are also available, and it is likely that future probes will be increasingly versatile. The probe is inserted through a 10/12 mm port (usually a periumbilical or epigastric port) and placed directly on the porta hepatis, perpendicular to the structures of the hepatoduodenal ligament. The probe is then moved to the cystic duct–CBD junction. The transverse image obtained

Figure 17 Laparoscopic cholecystectomy. Shown is a normal intraoperative cholangiogram.

should show the three tubular structures of the hepatoduodenal ligament in the so-called “Mickey Mouse head” configuration: the CBD, the portal vein, and the hepatic artery [see Figure 18]. As the probe is moved distally, it is rotated clockwise to allow identification of the distal CBD and the pancreatic duct where they unite at the papilla. Instillation of saline into the right upper quadrant can enhance acoustic coupling and improve visualization.

Because of its many advantages, intraoperative laparoscopic ultrasonography may eventually replace fluorocholangiography in this setting, particularly for surgeons who practice routine intraoperative evaluation of the CBD.³⁰ Although the learning curve for effective performance of laparoscopic ultrasound examination is not long, surgeons should receive expert mentoring and formal instruction in ultrasonography before attempting it. During the first few attempts, it may be instructive to perform intraoperative laparoscopic ultrasonography in conjunction with fluorocholangiography. It should be emphasized that intraoperative laparoscopic ultrasonography is not a replacement for intraoperative cholangiography if the purpose of the examination is to define an anomalous anatomy or to evaluate a suspected injury or leak.

Step 6: Dissection of the Gallbladder from the Liver Bed

The gallbladder is grasped near the cystic duct insertion and pulled down toward the right anterosuperior iliac spine, placing the areolar tissue between the gallbladder and liver anteriorly under tension. The areolar tissue is cauterized with an L-shaped hook dissector or spatula, and dissection is carried upward as far as possible for as long as there is sufficient exposure. When exposure begins to diminish, the cystic duct end of the gallbladder should be pulled up toward or over the left lobe of the liver to expose the posteroinferior attachments of the gallbladder. A two-handed approach by the surgeon

Figure 18 Laparoscopic cholecystectomy. A transverse intraoperative ultrasound scan of the hepatoduodenal ligament reveals a typical “Mickey Mouse head” appearance. Visible are the common bile duct (CBD), the common hepatic artery, and the portal vein.

facilitates this dissection. It is sometimes helpful to apply downward and lateral traction on the forceps grasping the fundus. Bleeding during this stage generally indicates that the surgeon has entered the wrong plane and dissection has entered the liver. Bleeding can usually be readily controlled with the electrocautery. In some difficult cases (e.g., an intrahepatic gallbladder), it may be prudent to leave some of the posterior wall of the gallbladder in situ and cauterize it rather than persist with an excessively bloody dissection.¹⁶

Dissection continues until the gallbladder is attached only by a small piece of peritoneum at the fundus. Before the last attachment to the gallbladder is completely divided, the vital clips are reinspected to ensure that they have not slipped off, and the operative field is checked for hemostasis and the presence of any bile leakage. The final attachment to the gallbladder is then divided. The gallbladder is placed over the right lobe of the liver and laterally so that it can be found again to be retrieved. The grasping forceps on the gallbladder should not be removed.

Perforation of the gallbladder The gallbladder may be accidentally breached at some point in the operation, with the result that bile and stones spill into the peritoneal cavity.^{31,32} Efforts should be made to suction the spilled bile, which accumulates in the suprahepatic space, the right subhepatic space, and the lower abdomen because of the patient's position. Each of these areas should be irrigated and the effluent aspirated until it is clear. Stones should be located and removed whenever possible. An effective way of removing small stones is to irrigate the subhepatic space copiously. Cholesterol stones usually float on the irrigation fluid and can then be suctioned through a 10 mm suction probe or through a 32 French chest tube passed through the 10 mm operating port. Unfortunately, small stones may be lost in the omentum or between bowel loops. In such cases, it is probably appropriate to leave the stones within the peritoneum rather than perform a laparotomy to attempt to retrieve them. However, there have been reports of serious morbidity, including intra-abdominal abscess, fistula, empyema, and bowel obstruction, resulting from lost stones.

If the gallbladder is perforated and it seems likely that multiple stones will be spilled, the surgeon should introduce a sterile bag into the peritoneal cavity, placing it close to the perforation. Spilled stones can then be transferred immediately into the bag. After the gallbladder is removed from the liver bed, it, too, is placed in the bag, affording some protection to the wound when it is removed from the abdominal cavity.

Step 7: Extraction of the Gallbladder

The laparoscope is moved to the epigastric port, and a large-tooth grasping forceps is inserted through the umbilical port to grasp the gallbladder at the area of the cystic duct. Under direct vision, the gallbladder is then retrieved and pulled out as far as possible through the umbilical port. If the gallbladder is small enough, it can be drawn right into the trocar sleeve, and it and the trocar can then be removed together. It is sometimes necessary to stretch the fascial opening with a Kelly clamp or to aspirate bile from the gallbladder. It is far preferable to enlarge the incision than to have stones or bile spill into the abdominal cavity from a ripped gallbladder. Enlargement of this incision is easier if initial access was obtained via the Hasson technique. All of

the other ports are then removed from the abdominal wall under direct vision to ensure that there is no bleeding. All residual CO₂ should be removed to prevent postoperative shoulder pain. The fascial opening at the umbilicus should be sutured closed to prevent subsequent herniation, and all skin incisions should be closed.

Need for drainage The decision to place a drain after laparoscopic cholecystectomy should be governed by the same principles applied to patients undergoing open cholecystectomy. There are two main indications for drainage: (1) the cystic duct was not closed securely, and (2) the CBD was explored by either a direct or a transcystic approach.

Drain placement is easily accomplished. A closed suction drain is inserted intra-abdominally through the 10 mm operative port. A grasping forceps placed through the right lateral port is used to pull one end of the drain out through the abdominal wall. The other end is then positioned according to the surgeon's preference, usually in the subhepatic space.

COMPLICATIONS

Intraoperative Complications

Veress needle injury A syringe must always be attached to the Veress needle, and fluid must be aspirated before insufflation is initiated: failure to do so may lead to insufflation into a vessel and consequently to massive gas embolism. If the aspirate from the syringe attached to the Veress needle contains copious amounts of blood, a major vascular injury may have occurred, and immediate laparotomy is indicated. Because the problem at this point is a needle injury, it can usually be repaired easily and without serious sequelae.

Puncture of the bowel by a Veress needle is usually signaled by aspiration of bowel contents through the needle. If this occurs, the needle should be withdrawn and the approximate course and direction of the puncture remembered. The initial trocar should then be inserted by means of the open technique, under direct vision, to ensure that the undersurface of the abdominal wall is free of adherent bowel. Once pneumoperitoneum is created, careful examination of the abdomen through the laparoscope is undertaken. In most cases, either further leakage of bowel contents, staining of the serosal surface with bowel contents, or an ecchymosis on the serosal surface of the bowel helps the surgeon locate the site of the bowel injury. If ecchymosis is present without spillage of bowel contents, the bowel loop should be marked with a suture and reinspected at the end of the procedure. If ongoing leakage of bowel contents is noted, the injured loop of bowel can be either repaired by means of laparoscopic suturing or grasped with an atraumatic forceps and gently withdrawn through an enlarged umbilical incision for suture repair. The bowel is returned to the peritoneal cavity, and the laparoscopic cholecystectomy is completed.

Improper placement of the Veress needle into the omentum, the retroperitoneum, or the preperitoneal space may be signaled by high inflation pressures, uneven distribution of the gas on percussion, or marked subcutaneous emphysema. If such misplacement goes unrecognized, creation of a safe intraperitoneal space is impossible, and subsequent blind insertion of the trocar may result in injury to an intraperitoneal structure.

Trocar injury Trocar injury to blood vessels or bowel is much more dangerous than Veress needle injury to the same structures. Major vascular injuries virtually never occur when trocars are placed under direct vision; however, they remain a potentially lethal—although rare—complication of percutaneous trocar insertion. If active bleeding follows removal of the trocar from the cannula, prompt laparotomy is mandatory; if bleeding passes unnoticed and insufflation begins, massive air embolism will result. At the time of laparotomy, both the anterior and the posterior wall of the vessel must be examined after proximal and distal control of the vessel have been obtained.

Bowel injuries can result from either percutaneous or open insertion of the initial trocar. With open insertion, the bowel injury should be immediately obvious and can be repaired after the injured bowel is pulled through an enlarged umbilical incision; laparoscopic cholecystectomy can then proceed. Bowel injuries caused by percutaneous insertion may occur even in the absence of abdominal wall adhesions and can be managed in the same way as those caused by open insertion. The one caveat is that it is possible to spear the bowel in a through-and-through fashion so that when the laparoscope is inserted through the trocar, the view is normal and the injury is not recognized. This type of injury can be diagnosed only if the laparoscope is repositioned to the operating port at some time during the procedure and the undersurface of the umbilical site is carefully examined. This step is mandatory during the course of the operation, preferably early.

Bleeding *Abdominal wall* Bleeding from the abdominal wall can usually be prevented by careful trocar placement. The abdominal wall should be transilluminated before percutaneous trocar insertion and the larger vessels avoided. If a vessel is speared, the cannula usually tamponades the bleeding reasonably effectively during the procedure.

Once the procedure is completed, each trocar is removed under direct vision. If bleeding follows the removal of a trocar, the puncture hole can be occluded with digital pressure to maintain pneumoperitoneum and the bleeding controlled by cauterization or suture repair. Alternatively, the surgeon may place a Foley catheter through the trocar site with a stylet, inflate the balloon, and place traction on the catheter for 4 to 6 hours; however, tissue ischemia can make this technique quite painful.

Omental or mesenteric adhesions Generally, omental adhesions can be bluntly teased from their attachments to the gallbladder, with the plane of dissection kept close to the gallbladder, where the adhesions are less vascular. Adhesions to the liver should be taken down with the electrocautery to prevent capsular tears. Persistent bleeding from omental adhesions is unusual but can be managed by means of electrocauterization (with care taken to avoid damage to the duodenum or colon) or the application of hemostatic clips or a pretied ligating loop.

Cystic artery branch Arterial bleeding encountered during dissection in the Calot triangle is usually from loss of control of the cystic artery or one of its branches. Biliary surgeons must be aware of the many anatomic variations in the vasculature of the gallbladder and the liver. Because the main cystic artery frequently branches, it is common to find more than one artery if dissection is maintained close to the gallbladder. If what seems to be the main cystic artery is small, a posterior

Figure 19 Laparoscopic cholecystectomy. Shown is an algorithm outlining a screening approach that is often useful when the patient shows signs (e.g., pain, fever, or ileus) that are suggestive of a postoperative intra-abdominal complication, such as fluid collection or bile leakage. ERCP = endoscopic retrograde cholangiopancreatography; MRCP = magnetic resonance cholangiopancreatography.

cystic artery may be present and may have to be clipped during the dissection.

Prevention of arterial bleeding begins by dissecting the artery carefully and completely before clipping and by inspecting the clips to ensure that they are placed completely across the artery without incorporating additional tissue (e.g., a posterior cystic artery or right hepatic artery). When arterial bleeding is encountered, it is essential to maintain adequate exposure and to avoid blind application of hemostatic clips or cauterization. The laparoscope should be withdrawn slightly so that the lens is not spattered with blood. The surgeon should then pass an atraumatic grasping forceps through a port other than the operating port and attempt to grasp the bleeding vessel. An additional trocar may have to be inserted for simultaneous suction-irrigation. Once proximal control is obtained, the operative field should be suctioned and irrigated to improve exposure. Hemostatic clips are then applied under direct vision; in addition, a sponge may be introduced

to apply pressure to the bleeding vessel. Conversion to open cholecystectomy is indicated whenever bleeding cannot be promptly controlled laparoscopically.

Liver bed Bleeding from the liver bed may be encountered when the wrong plane is developed during dissection of the gallbladder. Patients who have portal hypertension, cirrhosis, or coagulation disorders are at particularly high risk. Control of bleeding requires good exposure, accomplished via lateral and superior retraction of the gallbladder; hence, bleeding is most easily controlled before the gallbladder is detached from the liver bed. Most liver bed bleeding can be controlled with the electrocautery, and it should be controlled as it is encountered to allow exposure of the specific bleeding site. Either a hook-shaped or a spatula-shaped coagulation electrode is effective. If oozing continues, oxidized cellulose can be placed as a pack through the operative port and pressure applied on the raw surface of the liver. If needed, fibrin glue can be applied to the bleeding raw surface.

Postoperative Complications

If a patient (1) complains of a great deal of abdominal pain necessitating systemic narcotics, (2) has a high or prolonged fever, (3) experiences ileus, or (4) becomes jaundiced, an intra-abdominal complication may have occurred. Blood should be drawn for assessment of the white blood cell count, hemoglobin concentration, liver function, and serum amylase level. Abdominal ultrasonography may help diagnose dilated intrahepatic ducts and subhepatic fluid collections [see Figure 19].

Fluid collection or bile leakage When a significant fluid collection is seen, it should be aspirated percutaneously under ultrasonographic guidance. If the fluid is blood and the patient is hemodynamically stable and requires no transfusion, observation of the patient and culture of the fluid are usually sufficient. If the fluid is enteric contents, immediate laparotomy is indicated. If the fluid is bile and the patient is ill, immediate laparotomy should be considered; if the patient is stable and the appropriate facilities are available, MRCP or ERCP may

be performed to identify the site of bile leakage, determine whether obstruction is also present, and assess the integrity of the extrahepatic biliary tree. If the bile ducts are in continuity and the bile is coming from the cystic duct stump or a small lateral tear in the bile duct, ES, with or without stenting, usually controls the leak. Percutaneous placement of a drain under ultrasonographic guidance allows control of the bile leakage and measurement of the quantity of fluid present.

Fever Postoperative fever is a common complication of laparoscopic cholecystectomy. As noted, it may be indicative of a complication such as bile collection or bile leakage. Other common reasons for postoperative fever (e.g., atelectasis) should also be considered.

Abnormal liver function When postoperative blood tests indicate significantly abnormal liver function, possible causes include injury to the biliary tree and retained CBD stones [see Figure 20].³³ Cholangiography is required, even if it was performed intraoperatively. If MRCP or ERCP yields

Figure 20 Laparoscopic cholecystectomy. Shown is an algorithm outlining an approach to abnormal liver function test results after laparoscopic cholecystectomy. CBD = common bile duct; ERCP = endoscopic retrograde cholangiopancreatography; ES = endoscopic sphincterotomy.

normal results, observation is sufficient; the abnormalities may be attributable to a passed stone or drug-related cholestasis. If stones are present, ES can usually solve the problem. If ERCP demonstrates extravasation of bile, it is important to establish whether the CBD is in continuity. If the duct is interrupted, early reoperation, ideally at a specialized center, is the best option. If the duct is in continuity, endoscopic and radiologic techniques may successfully resolve the problem without substantial morbidity.^{34,35} Percutaneous drainage is instituted to control the fistula, and sphincterotomy or stenting is useful to overcome any resistance at the sphincter of Oddi. Any retained stones causing distal obstruction should also be removed. Major ductal injuries usually call for operative repair. When such an injury is identified at operation, the surgeon must decide whether to attempt repair immediately; this decision should be based on the surgeon's experience with reconstructive biliary surgery and on the local expertise available. At a minimum, adequate drainage must be established. Most major ductal injuries are not, in fact, identified intraoperatively. When such an injury is identified postoperatively, adequate drainage must be established and the anatomy of the injury clarified as well as possible before repair. MRCP or transhepatic cholangiography may be required to delineate the anatomy of the proximal biliary tree when ERCP does not opacify the biliary tract above the injury. If surgical repair is indicated, it should be performed by a surgeon experienced in complex biliary tract procedures. Often referral to a specialized center is the most appropriate decision, especially in the case of more proximal biliary injuries.

SPECIAL CONSIDERATIONS

Conversion to Laparotomy

Conversion from laparoscopy to laparotomy may be required in any laparoscopic cholecystectomy, in accordance with the judgment of the surgeon. The most common reason for such conversion is the inability to identify important anatomic structures in the region of the gallbladder. Distorted anatomy may be the result of previous operations, inflammation, or anatomic variations. Conversion may also be required because of an intraoperative complication [see Postoperative Complications, *above*]. Ideally, the surgeon would wish to convert before any complication occurs. It must be emphasized that conversion to open surgery should not be considered a failure or a complication. Rather, it should be considered a prudent maneuver for achieving the desired objective—namely, safe removal of the gallbladder. Accordingly, every patient consent obtained for a laparoscopic cholecystectomy must explicitly allow for the possibility of conversion to an open procedure. Attempts have been made to predict the probability of conversion on the basis of preoperative information.^{36,37} It is clearly useful to stratify patients according to the likelihood of conversion. This information is helpful in selecting patients for laparoscopic cholecystectomy in an outpatient versus hospital setting, in determining the resources required in the OR, and in assisting patients in planning their work and family needs around the time of surgery.

Factors found to be predictive of an increased probability of conversion include acute cholecystitis, either at the time of

surgery or at any point in the past; age greater than 65 years; male sex; and thickening of the gallbladder wall to more than 3 mm as measured by ultrasonography. Other factors more variably associated with an increased likelihood of conversion are obesity, previous upper abdominal operations (especially gastroduodenal), multiple gallbladder attacks over a long period, and severe pancreatitis. Factors not associated with an increased likelihood of conversion are jaundice, previous ES, previous lower abdominal procedures, stomas, mild pancreatitis, and diabetes.

On the basis of our data, a 45-year-old woman with no history of acute cholecystitis and no gallbladder wall thickening has a probability of conversion lower than 1%; such a patient is a good candidate for laparoscopic cholecystectomy in an outpatient setting. Conversely, a 70-year-old man with acute cholecystitis and ultrasonographic evidence of gallbladder wall thickening has a probability of conversion of about 30%; such a patient would be better managed in a traditional hospital environment.

Acute Cholecystitis

Laparoscopic cholecystectomy has been shown to be safe and effective for treating acute cholecystitis.^{38,39} There are, however, several technical problems in this setting that must be addressed if the procedure is to be performed with minimal risk. It should also be recognized that the probability of conversion to laparotomy is greatly increased in these circumstances. There appears to be no advantage to delaying surgery in patients with acute cholecystitis, even if rapid improvement is noted with nonoperative management.^{40,41} Many patients return within a short time with recurrent attacks, and delaying surgery does not reduce the probability of conversion.

Technical difficulties associated with cholecystectomy for acute cholecystitis include dense adhesions, the increased vascularity of tissues, difficulty in grasping the gallbladder, an impacted stone in the gallbladder neck or the cystic duct, shortening and thickening of the cystic duct, and close approximation of the CBD to the gallbladder wall.

The surgeon should not hesitate to insert additional ports (e.g., for a suction-irrigation apparatus) if necessary. Because the tense, distended gallbladder is difficult to grasp reliably, it should be aspirated through the fundus early in the procedure, as previously described. If the graspers fail to grasp the wall or cause it to tear, exposure of the Calot triangle can be achieved by propping up or levering the neck of the gallbladder and the right liver with a blunt instrument. A sponge can be used for this purpose, thereby reducing the potential trauma of the retraction. This maneuver is also useful when an impacted stone in the neck of the gallbladder prevents the surgeon from grasping the gallbladder in the area of the Hartmann pouch. Dense adhesions that may be present between the gallbladder and the omentum, duodenum, or colon should be dissected bluntly (e.g., with a suction tip). Because the tissues are friable and vascular, oozing may be encountered. Electrocauterization should be only sparingly employed until the vital structures in the Calot triangle are identified. Instead, the surgeon should move to another area of dissection, allowing most of the oozing to coagulate on its own. Liberal use of suction and irrigation will keep the operative field free of blood.

In the identification of anatomic structures, it is important to keep dissection close to the gallbladder wall, working down

from the gallbladder toward the Calot triangle. Dissection of the lower part of the gallbladder from the liver bed early in the operation may aid in identification of the gallbladder neck–cystic duct junction (analogous to an open, retrograde dissection). The surgeon should be aware that edema and acute inflammation may cause foreshortening of the cystic duct. If the anatomy cannot be identified, preliminary cholangiography through the emptied gallbladder may indicate the position of the cystic duct and the CBD.

Often the obstructing stone responsible for the acute attack is in the neck of the gallbladder; thus, the cystic duct will be normal and easily secured with clips. If the stone is in the cystic duct, it must be removed before the duct is clipped or ligated. A thickened, edematous cystic duct is better controlled by ligation with an extracorporeal tie or a ligating loop than by clipping. If closure of the cystic duct is tenuous, closed suction drainage is advisable. Obviously, conversion to open cholecystectomy is indicated if the anatomy remains obscure. Conversion should also be considered if no progress is made after a predesignated period (e.g., 15 minutes) because at this point, the surgeon is unlikely to make any headway.

CBD Stones

Identification of patients at risk About 10% of all patients undergoing cholecystectomy for symptomatic gallstones will also have choledocholithiasis. To select from the various diagnostic and therapeutic options for managing choledocholithiasis, it is helpful to know preoperatively whether the patient is at high, moderate, or low risk for stones. Patients with obvious clinical jaundice or cholangitis, a dilated CBD, or stones visualized in the CBD on preoperative ultrasonography are likely to have choledocholithiasis (risk > 50%). Patients who have a history of jaundice or pancreatitis, moderately elevated preoperative levels of alkaline phosphatase or bilirubin, or ultrasonographic evidence of multiple small gallstones are somewhat less likely to have choledocholithiasis (risk 10 to 50%). Patients with large gallstones, no history of jaundice or pancreatitis, and normal liver function are unlikely to have choledocholithiasis (risk < 5%).

Diagnostic and therapeutic options One argument for routine intraoperative cholangiography is that it is a good way of identifying unsuspected CBD stones. However, more selective approaches to diagnosing choledocholithiasis make use of preoperative cholangiography via MRCP, EUS, or, more invasively, ERCP [see 5:18 *Gastrointestinal Endoscopy*]. Preoperative identification of choledocholithiasis allows the surgeon to attempt preoperative clearance of the CBD by means of ES or intraoperative clearance during laparoscopy, depending on his or her expertise. Preoperative cholangiography is suggested when the patient's history and the results of laboratory and diagnostic tests suggest that there is a moderate or high risk of CBD stones. It is our practice to have patients at high risk for CBD stones undergo ERCP and ES if warranted. For patients at moderate risk, MRCP or EUS is done first, followed by therapeutic ERCP if CBD stones are identified. Intraoperative cholangiography can also be used to identify choledocholithiasis. ERCP with ES may result in pancreatitis, perforation, or bleeding and carries a mortality of approximately 0.2%.

When stones are detected during the operation, the options include laparoscopic transcystic duct exploration,

laparoscopic choledochotomy and CBD exploration, open CBD exploration, and postoperative ERCP with ES.^{10,42} If a single small (≈ 2 mm) stone is visualized, it can probably be flushed into the duodenum by irrigating the CBD via the cholangiogram catheter and administering glucagon, 1 to 2 mg intravenously, to relax the sphincter of Oddi. Even if a stone of this size does not pass intraoperatively, it will usually pass on its own postoperatively.

Laparoscopic transcystic CBD exploration *Access to the biliary tree* The cholangiogram is reviewed; the size of the cystic duct, the site where the cystic duct inserts into the CBD, and the size and location of the CBD stones all contribute to the success or failure of transcystic CBD exploration.^{43–45} For example, transcystic exploration is extremely challenging in a patient who has a long, spiraling cystic duct with a medial insertion. The size of the stones to be removed dictates the approach to the CBD: stones smaller than 4 mm can usually be retrieved in fluoroscopically directed baskets and generally do not necessitate cystic duct dilatation; larger stones (4 to 8 mm) are retrieved under direct vision with the choledochoscope.

A hydrophilic guide wire is inserted through the cholangiogram catheter into the CBD under fluoroscopic guidance. The cholangiogram catheter is then removed. If the largest stone is larger than the cystic duct, dilatation of the duct is necessary, not only for passage of the stone but also to allow passage of the choledochoscope, which may be 3 to 5 mm in diameter.

Dilatation is accomplished with either a balloon dilator or sequential plastic dilators. Because plastic dilators may cause the cystic duct to split, balloon dilatation is recommended. A balloon 3 to 5 cm in length is passed over the guide wire and positioned with its distal end just inside the CBD and its proximal end just outside the incision in the cystic duct. The balloon is then inflated to the pressure recommended by the manufacturer and observed closely for evidence of shearing of the cystic duct. The cystic duct should not be dilated to a diameter greater than 8 mm. Larger stones in the CBD may be either fragmented with electrohydraulic or mechanical lithotripsy, if available, or removed via choledochotomy.

Once dilatation is complete, the guide wire may be removed or left in place to guide passage of a choledochoscope or baskets. When the choledochoscope is used, a second incision in the cystic duct, close to the CBD, avoids the Heister valves and allows removal of the guide wire. If baskets are used, a 6 French plastic introducer sheath may be inserted through the trocar used for cholangiography into the cystic duct. This sheath is especially useful if multiple stones must be removed.

Fluoroscopic wire basket transcystic CBD exploration Stones smaller than 2 to 4 mm that do not pass with irrigation through the cholangiograph catheter after injection of glucagon can usually be retrieved by using a 4 French or 5 French helical stone basket passed into the CBD over a guide wire under fluoroscopic guidance. The baskets can be passed alongside the cholangiograph catheter or inserted via a plastic sheath replacing the cholangiograph catheter. The basket is opened in the ampulla of Vater, pulled back into the CBD, and rotated clockwise until the stone is entrapped. The stone and basket are then removed together. A Fogarty catheter should not be used, because the stones are likely to be pulled up into the hepatic ducts, where they are much more difficult to remove.

Endoscopic transcystic CBD exploration When stones are 4 to 8 mm in diameter, the helical stone basket wires are generally too close together to permit retrieval. Hence, choledochoscopic basketing is used. A videocholedochoscope with a working channel is either passed over the guide wire or inserted directly into the cystic duct. Because the usual laparoscopic grasping forceps may damage the choledochoscope, forceps with rubber-covered jaws should be used. The image from the choledochoscope can be displayed on the monitor by means of an audiovisual mixer (i.e., a picture within a picture) or displayed on a separate monitor.

Once the choledochoscope enters the cystic duct, warm saline irrigation is begun under low pressure to distend the CBD and provide a working space. The choledochoscope usually enters the CBD rather than the common hepatic duct. When a stone is seen, a 2.4 French straight four-wire basket is inserted through the operating port. The stones closest to the cystic duct are removed first by advancing the closed basket beyond each stone, opening the basket, and pulling the basket back, thereby trapping the stone. The basket is then closed and pulled up against the choledochoscope so that they can be withdrawn as a unit. Multiple passes may be required until the duct is clear. A completion cholangiogram is done to ensure that the duct is clear and to rule out proximal stones. The dilated, traumatized cystic duct is ligated with a ligating loop rather than a hemostatic clip. If drainage is required, a red rubber catheter can be inserted into the CBD via the cystic duct.

Because of the angle created by the cephalad and superior retraction of the gallbladder, it may be difficult to pass the choledochoscope into the proximal ducts. If a common hepatic duct stone is seen on the cholangiogram, the patient is placed in a steep reverse Trendelenburg position. In this position, any nonimpacted stones may fall into the distal duct for retrieval. It may be possible to pass the choledochoscope into the proximal ducts by applying caudal traction to the cystic duct so as to align it with the common hepatic duct. An additional access port in the right upper quadrant may be needed. If the cystic duct is long or spiraling or inserts medially, this measure may not be feasible, in which case, access must be obtained by means of choledochotomy.

Laparoscopic CBD exploration Large stones (> 1 cm), as well as most stones in the common hepatic ducts, are not retrievable with the techniques described above. Ductal clearance can be achieved via choledochotomy if the duct is dilated and the surgeon is sufficiently experienced.^{46,47} The anterior wall of the CBD is bluntly dissected for a distance of 1 to 2 cm. When small vessels are encountered, it is preferable to apply pressure and wait for hemostasis rather than use the electrocautery in this area. Adrenaline-soaked gauzes placed through the 12 mm umbilical port are very effective for this purpose. Two stay sutures are placed in the CBD. An additional 5 mm trocar is placed in the right lower quadrant for insertion of an additional needle driver. A small longitudinal choledochotomy (a few millimeters longer than the circumference of the largest stone) is made with curved microscissors on the anterior aspect of the duct while the stay sutures are elevated. A choledochoscope is then inserted, and warm saline irrigation is initiated. In most cases, baskets should suffice for stone retrieval; however, lithotripter probes and

lasers are available for use through the working channel of the choledochoscope. The choice of approach depends on availability and individual surgical experience.

Subsequently, a 12 or 14 French latex T tube is fashioned with short limbs, placed entirely intraperitoneally to prevent CO₂ from escaping, and positioned in the CBD. The choledochotomy is then closed with fine interrupted absorbable sutures. The first suture is placed right next to the T tube, securing it distally, and the second is placed at the most proximal end of the choledochotomy; lifting these two sutures facilitates placement of additional sutures. Intracorporeal knots are preferred to avoid sawing of the delicate tissues. The end of the T tube is then pulled out through a trocar, and cholangiography is performed after completion of the procedure.

Open Cholecystectomy

Open cholecystectomy is usually reserved for patients in whom the laparoscopic approach is not feasible or is contraindicated. As such, it is typically performed only in the most difficult situations or when additional maneuvers such as CBD exploration are anticipated. Conversion from the laparoscopic to the open approach is not considered a complication and does not represent failure. Rather, conversion to this time-honored and effective procedure represents the prudent judgment of a safe surgeon.

OPERATIVE TECHNIQUE

The choice of incision depends on the surgeon's experience and preference, along with patient factors such as previous surgical procedures and body habitus. Typically, open cholecystectomy is performed through a right subcostal (Kocher) incision, but it can also be approached through an upper midline incision or, less commonly, through a right paramedian or transverse incision. A mechanical retraction system should be used, if available, so that the hands of the participating surgeons are free; there is no good rationale for struggling to perform difficult biliary surgery with handheld retractors.

The abdomen is opened and then explored; the abdominal viscera are inspected and palpated, and a retraction system is put in place. Long curved or angled clamps, such as Kelly or Mixer, are placed on the gallbladder fundus and infundibulum for the application of gentle traction. The fundus is elevated and the infundibulum is pulled laterally and away from the liver [see Figure 21]. If the gallbladder is not too inflamed and edematous, the procedure may be performed similarly to the typical laparoscopic approach: the surgeon identifies and ligates the cystic duct and artery and then removes the gallbladder from the liver bed.

With more difficult open cases, the above technique may not be possible. In such cases, a retrograde or so-called fundus down approach is usually employed. Staying as close to the gallbladder wall as is possible, the surgeon uses electrocautery or sharp and digital blunt dissection to remove the gallbladder from the liver bed, continuing downward to the cystic duct and artery [see Figure 22]. Anatomic variations of the duct and artery must always be anticipated. These structures can be very difficult to identify and safely dissect in cases of severe inflammation and markedly edematous tissues. In such cases, palpation and gentle digital blunt dissection of the duct and artery between the thumb and index finger is useful [see Figure 23]. Opening the gallbladder to remove stones or aspirate bile or pus may be necessary when it is tense and distended or necrotic and gangrenous. As with laparoscopic cholecystectomy, it is critical to identify the cystic duct and artery and their anatomic relations to the gallbladder and CBD before division and to avoid injury to the CBD or common hepatic duct. The cystic duct and artery may be suture ligated or divided between clips. Stones found in the cystic duct should be gently milked back into the gallbladder.

SPECIAL CONSIDERATIONS

Cholangiography

The indications for cholangiography are the same as for laparoscopic cholecystectomy. Several techniques for the performance of cholangiography can be used. Usually, the same

Figure 21 Open cholecystectomy. (a) Shown are the resting positions of the cystic duct and the common bile duct (CBD) (with the Calot triangle closed). (b) Improper upward retraction of the Hartmann pouch lines up the CBD and the cystic duct so that one can easily encircle the CBD or clamp the cystic duct and the CBD. (c) Correct downward and rightward retraction opens the Calot triangle; dissection proceeds lateral to the CBD.

Figure 22 Open cholecystectomy. In so-called fundus down dissection, the fundus and infundibulum are retracted up and away from the liver while dissection is performed with electrocautery. Sharp dissection with scissors or scalpel and blunt digital dissection all may be used, at the surgeon's discretion.

technique as for laparoscopic cholecystectomy is employed; the cystic duct is ligated or clipped high near the infundibulum and incised just below this point for insertion of a cholangiography catheter, which is secured against leakage by another clip or ligature. Alternatively, the cystic duct can be divided near the infundibulum and the gallbladder removed; then the cystic duct is cannulated. Needle puncture cholangiography can also be performed via the cystic duct or the common duct. Once cholangiography is complete, the gallbladder is removed and sent for pathologic examination. The operative field is inspected for hemostasis and irrigated. Any bile leak is identified. Drains are not routinely placed but can be used at the surgeon's discretion. If drains are used, a closed suction Jackson-Pratt or similar drain is recommended; the drain should be brought out through a separate stab incision.

Open CBD Exploration

Open CBD exploration has become a rare procedure, but it remains a skill that surgeons require. If ERCP has failed or is not possible, if the surgeon does not have the experience and necessary tools to perform laparoscopic duct exploration, or if laparoscopic efforts have failed, then open exploration becomes necessary. Ductal stones are identified either preoperatively or intraoperatively by ultrasonography, cholangiography, or palpation.

Appropriate retraction and exposure are crucial. The anterior aspect of the duct is exposed over a distance of 1 to 2 cm, avoiding electrocautery during dissection. Two stay sutures of a 3-0 monofilament are placed lateral to the midline of the duct. The common hepatic duct is sharply opened with a No. 11 or No. 15 scalpel and longitudinally incised further with a Potts arteriotomy or similar scissors. When performing these maneuvers, the surgeon must respect the arterial blood

Figure 23 Open cholecystectomy. In patients with severe inflammation and edema, the surgeon must be cautious when approaching the Calot triangle during fundus down dissection. In such circumstances, digital palpation can be very helpful in safely identifying the cystic duct and artery.

supply of the duct, which courses laterally on either side of the duct in the 3 o'clock and 9 o'clock positions [see Figure 24]. In some cases, stones are immediately visible and can simply be plucked from the duct once it is opened. Flushing the duct with saline, proximally and then distally, through a 12 or 14 French Foley or red rubber catheter may also clear the duct of stones. The intravenous administration of 1 to 2 mg of glucagon will relax the sphincter of Oddi, which may help in the flushing of stones from the duct. In some cases, stones will be impacted within the duct and will require additional maneuvers. The Kocher maneuver (liberally mobilizing the lateral duodenum and head of the pancreas) will allow the surgeon to hold and palpate the duodenum, the head of the pancreas, and stones within the duct, facilitating instrumentation. Stone retrieval forceps, biliary Fogarty catheters, and wire baskets can all be employed to retrieve stones. A choledochoscope can also be used, either at the outset of exploration or for stone retrieval, if simpler maneuvers are not successful.

Either T tube cholangiography or choledochoscopy may be employed to confirm clearance of ductal stones. If no stones are present, primary closure of the choledochotomy has been successfully employed, although most surgeons will leave in place a 12 or 14 French T tube, which is brought out through a separate stab incision in the right lateral abdominal wall [see Figure 25]. If stone clearance is not achieved, a T tube is

Figure 24 Open common bile duct exploration. (a) The common bile duct is opened vertically between laterally positioned stay sutures. (b) A catheter is then used to irrigate and flush stones from the duct. If stones are impacted within the duct, they can be retrieved with Fogarty catheters, wire stone retrieval baskets, or stone retrieval forceps. The choledochoscope can be used if any of these methods fail or as the initial method of exploration.

Figure 25 Open common bile duct exploration. (a) After common bile duct exploration, a T tube is fashioned and is placed into the duct. (b) Interrupted 4-0 absorbable sutures are used to close the choledochotomy snug around the tube. Completion cholangiography may then be performed. The tube is brought out through the right abdominal wall, through a separate stab incision, and secured to the skin.

mandatory for decompression of the biliary tract and to provide a route for future duct instrumentation. The T tube is connected to a bag for free drainage. Several days later, cholangiography is repeated. If it shows good flow into the duodenum without obstruction, the tube may be clamped and removed at the 2-week mark. If there are retained stones, a more mature tract must be allowed to develop over 4 to 6 weeks for future instrumentation and stone retrieval. Retained

stones may require ERCP, percutaneous transhepatic instrumentation, T tube tract instrumentation, or combinations of these for removal.

Financial Disclosures: None Reported.

22 PROCEDURES FOR BENIGN AND MALIGNANT BILIARY TRACT DISEASE

Susan Logan, MD, MPP, and David Linehan, MD, FACS

Over the past several decades, advances in imaging technology have been made that allow more accurate diagnosis of biliary tract diseases and better planning of surgical procedures and other interventions aimed at managing these conditions. Operative techniques have also improved as a result of a better understanding of biliary and hepatic anatomy and physiology. The role of endoscopists and interventional radiologists in the management of benign conditions, as well as palliation of malignant disease, is also expanding. Accordingly, biliary tract surgery, like many other areas of modern surgery, is constantly changing.

In this chapter, we describe common operations performed to treat diseases of the biliary tract, emphasizing details of operative planning and intraoperative technique and suggesting specific strategies for preventing common problems. Complex biliary tract procedures should be performed only in specialized centers where experienced multidisciplinary teams, including hepatobiliary surgeons, endoscopists, interventional radiologists, and intensivists, collaborate to manage the special problems and requirements of patients undergoing such procedures.

Preoperative Evaluation

ANATOMY

Before embarking on any operation on the biliary tract, the surgeon must accurately define the relevant anatomy and extent of disease. Familiarity with the numerous variations of ductal anatomy is crucial [see *Figure 1a*]. In the prevailing pattern, the segment 6 and 7 ducts coalesce to form the right posterior sectional bile duct, and the segment 5 and 8 ducts join to form the right anterior sectional duct. The right anterior duct is usually oriented vertically, whereas the right posterior duct tends to follow a more horizontal course. The right anterior and posterior sectional ducts unite to form the right hepatic duct. Note that the posterior sectional duct crosses in front of the right anterior portal vein before joining the right anterior bile duct (Hjortsjo crook) [see *Figure 1b*]. Division of the right anterior portal pedicle too close to its origin may result in injury to the right posterior bile duct. The right hepatic duct runs a short extrahepatic course before joining the left hepatic duct at the hepatic confluence, forming the common hepatic duct. Similarly, in the prevailing pattern, the ducts draining segments 2 and 3 join to form the left lateral sectional duct. This duct then crosses behind the ascending portion of the left portal vein and joins the duct from segment 4 (also called the medial sectional bile duct) to form the left hepatic duct. The left hepatic duct runs a longer, usually horizontal, extrahepatic course at the base of segment 4b.

The above description is of the prevailing pattern of biliary anatomy, but the surgeon must be aware of several common variations, particularly those involving the right-sided ducts [see *Figure 1c*]. Not infrequently, one of the right sectional ducts crosses the midplane of the liver to drain directly into the left hepatic duct. If this variation is present and the surgeon performs a standard left hepatectomy, the right-sided duct(s) may be injured. The segment 8 duct may also drain into the posterior sectional duct. Other important variations include a low insertion of the right hepatic duct or an anomalous low insertion of a right sectional, segmental, or subsegmental duct directly into the common hepatic duct, the common bile duct, or even the cystic duct. Variations to the left ductal system most frequently involve variable numbers and sites of insertion of the segment 4 duct(s). Rarely, the segment 4 duct(s) may drain directly into the common hepatic duct or confluence.^{1,2}

Finally, familiarity with the plate-sheath system is essential to performing safe dissection at the hepatic hilum [see *Figure 1d*]. This system is composed of four thick, fibrous plates—hilar, umbilical, cystic, and arantian—of which the hilar plate is most important to the liver surgeon. The hilar plate lies mainly in the coronal plane, at the base of segment 4 and posterior to the vasculobiliary structures in the porta. Superiorly, however, the hilar plate curves anteriorly, along the posterior aspect of the quadrate lobe, and here it is superior to all structures in the porta hepatis, including the right and left bile ducts. As the three vasculobiliary structures pass through the hilar plate, they are “sheathed” within the same fibrous tissue and become a single unit above the plate. Identification of these structures as a single unit above the hilar plate is much simpler and safer than individually isolating each structure lower in the porta hepatis. To gain access to these sheathed pedicles above the hilar plate, the surgeon must dissect the upper border of the hilar plate away from the liver, a technique referred to as “lowering the hilar plate.”³

IMAGING STUDIES

High-quality ultrasonography is useful for confirming the presence of biliary dilatation, and duplex ultrasonography is excellent for assessing vascular involvement. However, ultrasonography is very user dependent and, even in experienced hands, is less helpful for determining resectability or the level or cause of obstruction. Multidetector computed tomography (MDCT) is noninvasive and provides excellent information regarding mass lesions, the presence or absence of ductal dilatation, the extent and level of duct obstruction, and the extent of vessel involvement. Multiphase computed tomography (CT) generates precise and reliable images of the relevant arterial, portal, and venous anatomy. Therefore, conventional

Figure 1 (a) The most common pattern of bile duct anatomy. (b) Hjortso crook. (c) Common variations of right hepatic duct anatomy: (left) right anterior or right posterior duct draining into left hepatic duct; (right) low insertion of right sectional duct. (d) Plate-sheath system of the liver.

angiography is no longer used to determine resectability. Magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP) can provide detailed images of biliary anatomy and have reported accuracy rates of 100% and 95%, respectively, for determining the location and cause of biliary obstruction. Direct cholangiography—percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP)—may supply additional information about ductal anatomy, is useful for providing tissue (e.g., brush cytology) for diagnosis, and allows drainage of the biliary tree prior to operation. When major liver resection is anticipated, liver volumetric analysis using three-dimensional reconstruction of axial CT images should also be performed to confirm adequate size of the future remnant liver.⁴

In the case of malignant diseases of the biliary tract, evidence of distant organ metastases remains a contraindication to operation. The resectability of locally advanced hilar cholangiocarcinoma depends on the extent of vasculobiliary involvement, the presence or absence of contralateral lobar atrophy, and the predicted size of the future remnant liver.⁵ Repair of biliary injuries should be deferred in the setting of cholangitis, intra-abdominal infection, and sepsis [see Repair of Biliary Injuries, below].

MANAGEMENT OF BILIARY OBSTRUCTION

Jaundice by itself does not increase operative risk, and we do not routinely perform preoperative biliary drainage in all

patients with jaundice.⁶ However, long-standing biliary obstruction has secondary effects that may increase perioperative morbidity and mortality. In the presence of these secondary effects, we recommend elective preoperative biliary decompression.

Infection

Patients with cholangitis, whether spontaneous or induced by duct instrumentation (via PTC or ERCP), should be treated with biliary drainage and appropriate antibiotics until they are infection free. We recommend antibiotic treatment and postponement of operation for at least 3 to 4 weeks. Rarely, antibiotics and endoscopic or transhepatic drainage are not immediately effective, and patients with biliary tract infection (e.g., associated with choledocholithiasis) may require urgent surgical decompression. Broad-spectrum antibiotics, including coverage of anaerobic organisms, should be administered preoperatively.

Renal Dysfunction

The pathogenesis of renal failure in the setting of obstructive jaundice is multifactorial. Extracellular water depletion, increased plasma renin and aldosterone activity, a paradoxical increase in atrial natriuretic peptide, and myocardial dysfunction are all thought to contribute to renal insufficiency in jaundiced patients.⁷ Because the combination of a high bilirubin level and hypovolemia is a significant risk factor for acute renal failure, patients with biliary obstruction should be well hydrated before receiving intravenous contrast agents or

undergoing operative procedures. In patients with acute renal dysfunction secondary to biliary obstruction, decompression of the bile duct until renal function returns to normal is advisable before any major elective procedure for malignant disease.

Impaired Immunologic Function and Malnutrition

In patients with long-standing biliary obstruction, absence of bile salts in the gut lumen may lead to severe malnutrition and contribute to impaired immune function.⁸ Decompression of the bile duct until immune function and nutritional status are restored to normal is indicated before any major elective procedure is undertaken. This may take as long as 4 to 6 weeks.

Coagulation Dysfunction

Prolonged bile duct obstruction may lead to significant deficits in vitamin K–dependent clotting factors. These deficits should be corrected with fresh frozen plasma and vitamin K before an operative procedure is begun. Even if there is no measurable coagulation dysfunction, vitamin K should be given to all patients with obstructive jaundice at least 24 hours before operation to replenish their depleted vitamin K stores.

Projected Major Liver Resection

If resection of an obstructing bile duct tumor is likely to necessitate major liver resection (e.g., a right trisectionectomy), we recommend unilateral decompression of the liver segments that are to be retained. Unilateral drainage is usually sufficient to normalize serum bilirubin and allows atrophy of the undrained segments to occur, along with concomitant hypertrophy of the future liver remnant.

Operative Planning

GENERAL TECHNICAL CONSIDERATIONS

Place the patient in the supine position on an operating table that can be rotated, tilted, and elevated. Equipment for fluoroscopy, intraoperative ultrasonography and choledochoscopy should be available during major resections. Access to a pathology department that can perform cytologic or frozen-section examination of tissue is essential in operations for malignant disease.

A right subcostal incision with vertical midline extension provides excellent exposure for most open procedures on the liver and biliary tract. For more extensive resections or reconstructions, the right subcostal incision can be extended laterally below the costal margin and across the midline to the left as a chevron incision. A vertical midline incision may give sufficient exposure in very thin persons. In any case, the incision must be long enough to allow sufficient visualization and as much mobilization of the liver as is necessary for safe performance of the procedure.

Adequate exposure and lighting are essential. The best retractors are those that can be fixed to the table while remaining flexible in terms of placement and angles of retraction. Retractor blades should be positioned to lift the ribcage anteriorly and cephalad and to pull the right abdominal wall laterally.

Locating the hepatoduodenal ligament and dissecting the structures in the porta hepatis are straightforward in patients who have never had an abdominal operation. However, in patients who have undergone previous operations, there may be considerable obliteration of planes. The following are suggestions for gaining access to the subhepatic space in patients who have had previous abdominal procedures:

1. Use the falciform ligament as a landmark. In reoperative surgery, the key to opening up the upper abdomen is the falciform ligament. This structure should be found immediately after the opening of the abdominal wall and retracted superiorly. The omentum, the colon, and the stomach are then dissected inferiorly, and a plane that leads to the hepatoduodenal ligament and the porta hepatis is thereby opened.
2. Take the right posterolateral approach. When the colon and the duodenum are densely adhered to the undersurface of the right liver, separation may be difficult. In most patients, an open space remains that can be approached by sliding the left hand posteriorly to the right of these adhesions and into the (usually open) subhepatic space in front of the kidney and behind the adhesions. Anterior retraction allows identification of the adherent structures by palpation and permits dissection of the adhesions in a lateral-to-medial direction. The undersurface of the liver is thus cleared, and the hepatoduodenal ligament can be approached.
3. Take the lesser sac approach. Ordinarily, the foramen of Winslow is open, and the left index finger can be passed through it from the right subhepatic space. When the foramen of Winslow is obliterated, however, one should approach it from the left, dividing the lesser omentum and passing an index finger from the lesser sac behind the hepatoduodenal ligament to reopen the foramen of Winslow by blunt dissection.

For a discussion of techniques to aid in the safe exposure of the porta hepatis in patients who have sustained a bile duct injury or have had previous biliary operations, refer to the section below on repair of biliary injuries: exposure of the porta hepatis.

General Guidelines for Biliary Anastomoses

As a rule, biliary anastomoses, whether of duct to bowel or of duct to duct, heal very well provided that the surgeon adheres to the following principles: (1) preservation of adequate blood supply, (2) avoidance of tension, (3) accurate placement of sutures with mucosa-to-mucosa apposition, and (4) construction of anastomoses of adequate caliber. In preparing the bile duct for anastomosis, it is essential to define adequate margins while avoiding excessive dissection that might compromise the blood supply to the duct. In repairs that follow acute injuries, it is important to resect crushed or devascularized tissue; however, in late repairs, it is not necessary to resect all scar tissue as long as an adequate opening can be made in the proximal obstructed duct through normal healthy tissue and as long as mucosa, rather than granulation tissue, is present at the duct margin. The length of the corresponding opening in the jejunal loop should be significantly smaller than the bile duct opening because the bowel opening tends to enlarge during the procedure.

Certain principles of suture placement apply to all biliary anastomoses. Mucosa-to-mucosa apposition is essential for good healing and the prevention of late stricture.⁹ Sutures should be of an absorbable, synthetic monofilament material and should be as fine as is practical (e.g., 5-0 for a normal duct and 4-0 for a thickened duct). Because the bile duct wall has only one layer, biliary anastomoses should all be single layer. Sutures should pass through all layers of the bowel, taking sizable bites of the seromuscular layer and much smaller bites of the mucosa, and should take moderate-sized (1 to 3 mm, depending on duct diameter) bites in the bile duct. Interrupted sutures are used when access is difficult or the duct is small; continuous sutures are used when access is easy and the duct is larger. Sutures should be securely placed but should not be so tight as to injure the tissues. Magnification with loupes is useful when anastomosing small ducts. With the exception of repair of high, complex bile duct injuries, we do not routinely place stents for biliary anastomoses. Some studies suggest that placement of drains is not necessary after biliary operations.^{10,11} Nevertheless, it is currently our practice to place a drain at the time of the operation and to remove the drain within 2 to 3 days if the output does not show evidence of a bile leak.

When the bile duct opening has a vertical configuration (as in side-to-side choledochoduodenostomy or choledochojejunostomy), we place stay sutures inferiorly and superiorly in the duct and at corresponding points in the intestine. Traction is placed on these sutures to line up the adjacent walls. One side of the anastomosis is done first; the bowel is then rotated 180°, and the other side is completed [see Figure 2]. This maneuver may be facilitated by retracting the first interrupted posterior stitch to the opposite side to serve as a pivotal stitch. We recommend sewing about two thirds of the first wall and two thirds of the second, leaving the anterior third of the circumference (the easiest part) to be closed last. For end-to-side choledochojejunostomy, or when the bile duct opening lies transversely, as in bifurcation reconstruction, lateral stay sutures are placed first, and the posterior wall stitches are placed from inside the lumen. If interrupted sutures are used, they are all placed individually before any of them are tied, with the untied tails carefully clamped and arranged in order. When the posterior wall sutures have been tied, the anterior wall can then be sutured with either continuous or interrupted sutures [see Figure 3].

When the intended anastomosis will be to a very small-caliber or intrahepatic duct, and access is particularly difficult because of some combination of an unfavorable position, a previous scar, or a stiff liver that is difficult to retract, another technique may be useful. Beginning left to right, place all of the anterior wall stitches (inside to outside) into the duct. Clamp each suture and place them in order on a single retracting forceps with the needles left attached. Retract the sutures superiorly to expose the posterior wall of the duct [see Figure 3c]. Again, working left to right, place the posterior stitches inside to outside through the bowel wall and outside to inside into the duct. Remove the needles at the completion of each stitch, clamp each suture, and keep them in order as described for the anterior row. When all of the posterior stitches have been placed, carefully appose the bowel wall to the bile duct, tie all but the two corner stitches in order, and

cut the sutures. Leaving the corner stitches (at 3 and 9 o'clock) loose facilitates accurate placement of the lateral and medial stitches of the anterior wall. Finally, place the anterior wall stitches inside to outside on the bowel, sequentially clamp the stitches until the last stitch is placed, and then tie the stitches in order and cut the sutures.⁹

When the duct is very small, three additional techniques may be useful for increasing the size of the lumen:

1. An anterior longitudinal incision can be made in a small common bile duct (CBD) and the sharp corners trimmed to enlarge the opening [see Figure 4a].
2. If the cystic duct is present alongside a divided CBD, an incision can be made in the shared wall to create a single larger lumen [see Figure 4b].
3. If the bifurcation has been resected, two small ducts can be brought together and sutures placed into their adjoining walls to form a single larger lumen as long as the space between the ducts is small and the ducts can be brought together without tension [see Figure 4c]. If the ducts cannot be brought together without tension, more than one anastomosis must be created.

Construction of a Roux Loop

When the jejunum is used for long-term biliary drainage, we prefer a 60 cm Roux loop to prevent reflux of small bowel contents into the biliary system. In the creation of the loop, it is important to select a segment of jejunum with a well-defined vascular arcade that will be long enough to support a tension-free anastomosis. If access to the biliary system will be required in the future (e.g., in an operation for recurrent intrahepatic stones), the loop should be long enough to allow one to place a tube jejunostomy, fixing the loop to the abdominal wall with nonabsorbable sutures. The site of attachment should be marked with metallic clips to facilitate future percutaneous puncture, cannulation, and removal of recurrent or persistent stones. The tube can be removed after postoperative imaging studies confirm that the biliary tree is free of stones.

Choledochoduodenostomy

Choledochoduodenostomy is a relatively straightforward end-to-side (or sometimes side-to-side) biliary-enteric bypass procedure that is useful in certain restricted circumstances. It is most commonly used in patients with multiple bile duct stones when there is concern about leaving residual stones at the time of CBD exploration, as well as in patients with recurrent bile duct stones when endoscopic papillotomy either cannot be done or has been unsuccessful. Choledochoduodenostomy has the advantage of being simpler and safer than transduodenal sphincteroplasty. It is also used in patients with benign distal biliary obstruction (e.g., from chronic pancreatitis or a very low bile duct injury) and occasionally in patients with malignant distal CBD obstruction whose life expectancy is limited. Choledochoduodenostomy works best if the CBD is at least 1 cm in diameter.

CONTRAINDICATIONS

Choledochoduodenostomy should not be used in patients with actual or potential duodenal obstruction.

Figure 2 Technical issues in biliary anastomosis. Shown is a side-to-side choledochojejunostomy using a vertical incision in the bile duct. The same technique can be used for choledochoduodenostomy or end-to-side choledochojejunostomy. (a) Inferior and superior corner continuous sutures are placed. (b) One side of the anastomosis is sewn first (here, the right side). (c) The bowel is rotated 180° so that the other side is exposed. The other side of the anastomosis is then sewn (here, the left side).

OPERATIVE TECHNIQUE

Mobilize the duodenum to allow approximation to the CBD without tension. Ordinarily, the first part of the duodenum can easily be rolled up against the CBD; however, in patients who have chronic pancreatitis or have previously undergone an abdominal procedure, extensive Kocherization may be required. If satisfactory approximation is not achieved with this maneuver, a choledochojejunostomy should be performed instead.

Expose the CBD as described elsewhere. Make longitudinal incisions in both the duodenum and the duct [see Figure 2] and create the anastomosis as described previously [see Operative Planning, General Technical Considerations, General Guidelines for Biliary Anastomoses, above].

COMPLICATIONS

Late closure or stricture of the anastomosis may occur if the CBD is small, has inadequate blood supply, or malignant

disease is present. Consider alternative methods of biliary decompression in these situations.

Cholangitis related to the presence of food in the CBD distal to the anastomosis (so-called sump syndrome) is an uncommon occurrence. The larger the anastomosis, the smaller is the likelihood that this complication will occur.

Cholecystojejunostomy

Cholecystojejunostomy may be performed to treat malignant biliary obstruction in selected patients whose lesions are found to be unresectable at operation and whose life expectancy is short.

CONTRAINDICATIONS

Absolute contraindications to this drainage procedure include obstruction above the cystic duct entry point, evidence of cholecystitis, and benign causes of biliary

Figure 3 Technical issues in biliary anastomosis. Shown is an end-to-side choledochojejunostomy using a transverse opening in the bile duct. This technique can be used at any level. (a) Corner sutures and posterior wall sutures are all placed before being tied. (b) The posterior wall is completed, and the anterior wall is sewn. (c) In difficult cases, the anterior wall sutures may be placed first and then retracted superiorly.

obstruction (i.e., patients with normal life expectancy). This operation is not the preferred procedure for long-term decompression.

OPERATIVE TECHNIQUE

Step 1: Verification of Feasibility of Procedure

The cystic duct must be patent. Its junction with the CBD must be at least 1 cm above the tumor obstruction [see

Figure 5]. The suitability of the anatomy for cholecystojejunostomy should have been verified by preoperative cholangiography; if not, intraoperative cholangiography via the gallbladder or the CBD is mandatory. If one still cannot be certain that the operation is feasible, the CBD should be opened and a choledochoenterostomy performed. The finding of a bile-filled gallbladder is not sufficient evidence that the patient is a suitable candidate for a cholecystojejunostomy. The gallbladder must be normal: there should be no evidence of cholecystitis or stones. Verify normal status by inspection, palpation, and, if necessary, needle cholecystography.

Step 2: Preparation for Anastomosis

Select a site near the fundus for the anastomosis and anchor an appropriate, tension-free segment of proximal jejunum to the gallbladder with two fine stay sutures. Between the two stay sutures, make a 2 cm transverse opening in the gallbladder and a corresponding longitudinal incision in the antimesenteric border of the bowel.

Step 3: Anastomosis

Create a single-layer anastomosis using a continuous monofilament absorbable suture or a stapler.

COMPLICATIONS

Bile leakage may occur if there is excessive tension on the anastomosis. In addition, jaundice may persist if there is unrecognized cystic duct obstruction resulting from inflammation or an unnoticed stone in the cystic duct or the gallbladder. Recurrent jaundice is usually the result of extension from an obstructing tumor that has involved the cystic duct–CBD junction.

Choledochojejunostomy

Choledochojejunostomy, one of the most commonly performed biliary tract procedures, is done to provide biliary drainage after CBD resection, repair of ductal injury, or relief of obstruction caused by a benign or malignant stricture. To reduce the likelihood of reflux of intestinal contents into the biliary tract, we prefer to use a 60 cm Roux-en-Y jejunal limb for the anastomosis [see Operative Planning, General Technical Considerations, Construction of a Roux Loop, above].

When the operation is performed after CBD resection, an end-to-side choledochojejunostomy using the proximal transected duct is preferred as long as adequate vascularization of the transected bile duct is confirmed. When the operation is performed for bile duct obstruction resulting from tumor or stricture and no resection has been performed, a side-to-side anastomosis is constructed.

OPERATIVE TECHNIQUE

Step 1: Preparation for Anastomosis

Preparation for an end-to-side anastomosis includes resection of any crushed or devitalized bile duct tissue. The CBD should be trimmed back to healthy, viable, bleeding duct wall.

If a side-to-side anastomosis is being performed for stricture or tumor, the proximal duct is almost always dilated and

Figure 4 Technical issues in biliary anastomosis. Shown are three methods of enlarging a small duct. (a) An anterior longitudinal incision can be made in the duct wall. (b) A wall shared by the common bile duct and the cystic duct can be divided. (c) Adjoining walls of two small ducts can be sutured together to make a single opening for anastomosis.

has thicker walls, facilitating a vertical incision on the anterior surface. When the procedure is being done for malignant disease, the incision should be made as high as possible above the malignancy to delay the eventual obstruction of the anastomosis by tumor growth.

Step 2: Anastomosis

When the duct is large, a secure, tension-free anastomosis is easily constructed by means of the techniques previously illustrated. When the duct is small, extra effort must be made to place sutures carefully to prevent narrowing of the lumen.

TROUBLESHOOTING

Injured ducts must be adequately débrided, even if this means extending the resection of the duct to the bifurcation. However, preservation of the blood supply to the CBD is essential. Avoid extensive mobilization of the duct from the surrounding tissues to prevent injury to the ductal blood supply. Finally, longitudinal incisions should not be made in the medial or lateral (3 and 9 o'clock) portions of the CBD, where the major longitudinal blood supply is located.

Meticulous surgical technique is critical for ensuring good healing and preventing stricture. Use the finest suture material that will do the job and employ magnifying devices to facilitate accurate placement of sutures. Routine postoperative stenting is unnecessary, but stents may be helpful in those very rare cases in which mucosal apposition cannot be accomplished. In these situations, sutures may have to be placed in surrounding liver or scar tissue in much the same way as in a Kasai procedure.¹² In difficult cases of proximal

stricture, the surgeon may be forced to incise and lower the liver plate and seek out viable intrahepatic ducts for anastomosis [see Repair of Biliary Injuries, *below*].

COMPLICATIONS

The main complications of a choledochojejunostomy are bile leakage, late stricture, and recurrent jaundice as a result of tumor extension [see Cholecystojejunostomy and Choledochoduodenostomy, *above*].

Choledochal Cyst Resection

Choledochal cysts are generally categorized according to the Todani classification [see Figure 6]. More than 80% are type I cysts that involve the CBD in its accessible portion. The following discussion addresses the resection of type I cysts and those type IV cysts that include the proximal right or left hepatic ducts.

Most choledochal cysts are associated with an abnormal junction of the pancreatic duct and the distal CBD. Preoperative cholangiography to clarify the anatomy is important for preventing injury to the pancreatic duct, especially when an intrapancreatic resection is required. Occasionally, intraoperative cholangiography is needed to clarify abnormal anatomy. Patients may be symptomatic as a result of stones within the cyst, infection, or malignancy, any of which is an indication for operation. The increased risk of bile duct malignancy associated with choledochal cysts, and the high mortality associated with cholangiocarcinoma, is justification for prophylactic cyst resection even in asymptomatic patients.

Figure 5 Cholecystojejunostomy. Cholangiography is essential for determining whether the anatomy is suitable (a) or unsuitable (b, c) for the procedure.

The objectives of treatment are (1) to remove the cyst completely, along with the gallbladder and any stones that remain in the bile ducts proximal to the cyst, and (2) to restore biliary-enteric drainage. Resection of a choledochal cyst may be made more difficult by several factors, such as previous operations, recurrent bouts of infection and inflammation in the cyst, and portal hypertension, which may develop as a result of long-standing cholangitis or portal vein thrombosis.¹³

OPERATIVE TECHNIQUE

Resection of a choledochal cyst may be difficult, especially if inflammation is present. In addition, dissection of a choledochal cyst in its intrapancreatic portion is hazardous because of the vascularity of this region and the difficulty identifying anatomic structures.

Step 1: Clarification of Anatomy

The proximal and distal extent of the cyst and the presence or absence of stones or tumor may be determined preoperatively, as noted, but in many cases, intraoperative verification of the findings is necessary. Intraoperative cholangiography can be carried out by inserting a catheter through the gallbladder, by directly needling the cyst, or both. If cholangiography does not yield an accurate definition of the anatomy of the cyst, the cyst may then be opened anteriorly and digital exploration and choledochoscopy used to clarify the proximal and distal extent of the cyst.

Step 2: Mobilization of the gallbladder

If the gallbladder is still in place, dissect it free of the liver, leaving it attached to the cyst via the cystic duct, and retract the gallbladder to the right.

Step 3: Distal Dissection

Early distal division of the cyst facilitates the posterior dissection and allows mobilization of the duct to better define the proximal extent of the cyst. Dissect distally along the wall of the cyst until the junction of the cyst with the normal portion of the CBD is reached. If the intrapancreatic portion of the CBD is involved, the cyst must be separated from pancreatic tissue. A number of small vessels must be individually identified and ligated to minimize the risk of early or delayed bleeding. If the cyst is close to the pancreatic duct junction, one must exercise considerable care not to injure the pancreatic duct. Transect the distal bile duct. Place a clamp on the proximal cut end of the duct to assist with retraction and oversew the distal cut end using fine monofilament absorbable suture, being careful not to injure the pancreatic duct.

Step 4: Mobilization of Cyst

Vascularity in the region and the presence of inflammation may render dissection difficult. Rather than cleaning off the hepatic artery and the portal vein and dissecting them off the cyst, find a plane immediately adjacent to the wall of the

Figure 6 Choledochal cyst resection. Illustrated is the Todani classification of choledochal cyst.

cyst and remain close to it [see Figure 7]. This approach differs significantly from the corresponding approach in resection of a bile duct malignancy [see Resection of Middle-Third and Proximal Bile Duct Tumors, Operative Technique, below]. If necessary, open the cyst with a vertical anterior cystotomy and continue the dissection with direct visualization of the inside of the cyst to yield a more accurate definition of its boundaries. Clear the cyst circumferentially, separating the cyst from the hepatic artery, the portal vein, and any remaining soft tissue in the hepatoduodenal ligament.

Step 5: Proximal Dissection

If the proximal common hepatic duct is normal (as in a type I cyst), transect the duct above the cyst. If the cystic dilatation includes the bifurcation (as in a type IVa cyst), a small button of proximal cyst is usually left attached to the intrahepatic ducts [see Figure 8].

Step 6: Reconstruction

Reconstruction is accomplished via an end-to-side anastomosis to a Roux jejunal loop to minimize the likelihood of reflux of enteric contents into the biliary tract. Stenting is not required, but we recommend draining the area with closed suction drains, especially if an intrapancreatic resection has been done.

Figure 7 Choledochal cyst resection. Illustrated is the proper plane of dissection in removal of a choledochal cyst. If necessary, dissection can be done with a finger inside the cyst.

Figure 8 Choledochal cyst resection. If a cyst extends proximally past the bifurcation (e.g., a type IVa cyst), it may be necessary to open the cyst widely to identify the hepatic duct orifices. A small button of cyst wall is left attached to the hepatic ducts.

TROUBLESHOOTING

If dissection of the cyst is carried distally into the pancreas, care must be taken to keep from injuring the pancreatic duct. Transect the cyst as distally as possible and carefully oversew the end with absorbable sutures. Intraoperative cholangiography and/or preoperative MRCP are useful to confirm the relationship of the cyst and the CBD to the pancreatic duct.

If the cystic process extends to include the bifurcation (type IVa), the hepatic ducts should be identified from within the cyst and their orifices preserved by leaving a small button of cyst wall in situ; this is preferable to performing an intrahepatic dissection to remove the entire cyst. The presence of this button simplifies and facilitates the anastomosis to the Roux loop. Note that liver resection for choledochal cyst is rarely justified unless there is evidence of a solid mass or papillary excrescence emanating from the cyst mucosa.

COMPLICATIONS

Bleeding and pancreatitis are the main early complications of cystectomy. These can be largely prevented by meticulous dissection and ligation of all fine bleeding vessels as well as tissue adjacent to an intrapancreatic cyst. Late stricture of the anastomosis is an uncommon complication but may occur, especially if a small button of proximal cyst is left in place for the anastomosis; this particular complication is considered an acceptable hazard in a difficult situation.

OUTCOME EVALUATION

The immediate expected outcome is the relief of pain, jaundice, and cholangitis and the return of liver function to normal. The long-term expected outcome is the absence of

any recurrence of symptoms of stone disease, cholangitis, or malignancy. Because of the rarity of this condition, no good data on the recurrence rate of problems are available, but in our experience, the need for reintervention is rare.

Resection of Middle-Third and Proximal Bile Duct Tumors

The most common bile duct tumor is adenocarcinoma. Because this tumor responds poorly to irradiation and chemotherapy, surgical resection offers the best opportunity for cure. Unfortunately, many patients present with unresectable local disease and distant metastasis, and only palliative interventions are warranted. The appropriate operative approach depends on the location and extent of the tumor [see Figure 9]. Tumors in the distal third of the CBD (the pancreatic portion) are treated by means of a pancreaticoduodenectomy that includes bile duct and periductal tissues right up to the bifurcation. Those in the middle third or the proximal third are treated by means of bile duct resection, often with concurrent liver resection.

Certain basic principles underlying bile duct resection for tumor must be followed. First, the proximal extent of the tumor must be identified so that the correct procedure can be planned. Preoperative PTC is usually not required for staging if high-quality MRI and MRCP are available. With the exception of the clinical circumstances outlined previously [see Management of Biliary Obstruction, *above*], we do not routinely place preoperative biliary drainage tubes.

Second, given that bile duct tumors spread by local extension to lymphatics, along perineural spaces, and along the biliary radicles directly into the liver, wide local excision beyond the visible edges of the tumor is required in the performance of curative resections. In proximal tumors, such excision necessitates resection of the adjacent segments of the liver. The principles of en bloc resection beyond tumor margins must be closely adhered to: dissection into or even close to the tumor must be avoided.¹⁴

Third, intraoperative biopsy of the tumor is unreliable because of the difficulty of making a firm pathologic diagnosis on the basis of frozen-section examination.

Figure 9 Resection of middle-third and proximal bile duct tumors. The appropriate operation depends on the location and extent of the tumor. (a) Broadly, tumors may be localized to the proximal third, the middle third, or the distal third of the biliary tract. (b through f) Proximal tumors may be further categorized according to the Bismuth classification.

Finally, given that liver resection is required in most cases, one must be careful to preserve enough healthy liver tissue to allow regeneration of the remnant.¹⁵ If there has been long-standing obstruction, biliary drainage on the side to be preserved is important for recovery of function in that portion of the liver. Some surgeons advocate preoperative portal vein embolization on the contralateral side to stimulate hepatic regeneration in the segments to be preserved, especially if the future remnant is marginal in size. Often this is unnecessary, however, because of lobar atrophy attributable to ipsilateral portal vein involvement and compensatory contralateral hypertrophy.

On the whole, we are aggressive in treating proximal tumors for two main reasons: (1) the accompanying liver resection can now be done with low morbidity, and (2) this more radical approach has been shown to yield improved long-term results.⁵ For middle-third or type I proximal tumors, we favor resection of the bifurcation in conjunction with intrahepatic cholangiojejunostomy. For types II, III, and IV, we recommend additional liver resection: a right trisectionectomy (resection of segments 4, 5, 6, 7, and 8, along with the caudate lobe) for types II, IIIa, and IV and a formal left hepatectomy (resection of segments 1, 2, 3, and 4) for type IIIb. There is some controversy as to whether patients with these complex proximal biliary tumors have a better chance of long-term survival with liver transplantation than with radical resection because of the high incidence of positive microscopic margins. This controversy has yet to be resolved, but we prefer radical resection when feasible. Transplantation for hilar cholangiocarcinoma should be performed only in the context of an approved clinical trial.

OPERATIVE TECHNIQUE

Step 1: Assessment of Resectability

Assessment of resectability begins with an evaluation of the patient's fitness and exclusion of underlying liver disease (i.e., cirrhosis and portal hypertension). The next step is to confirm the radiographic appearance of resectability. Radiographic evidence of metastatic disease is an absolute contraindication to resection. In the absence of metastatic disease, the resectability of hilar cholangiocarcinoma is predicted by the extent of vasculobiliary involvement and the presence or absence of contralateral lobar atrophy. In general, if the tumor involves only the ipsilateral portal vein and/or bile ducts, it may be resectable; if the tumor involves the contralateral portal vein and/or contralateral secondary bile ducts, it is generally not resectable.⁵ Finally, if curative resection requires major hepatectomy, the future remnant liver must be of adequate size to prevent postoperative liver failure.

Before any dissection of the tumor or the CBD is done, conduct a careful search for peritoneal metastases. Evaluate spread within the liver by palpation. Palpate for suspicious lymph nodes in the immediate and secondary drainage areas. Biopsy any suspicious areas outside the planned resection margins and send this for frozen-section analysis. If the frozen section confirms that tumor is present outside the planned resection area, palliative stenting or a bypass procedure is indicated.

During dissection, determination of resectability is often difficult, especially with respect to assessment of tumor extension into the liver and the degree of vessel involvement.

Therefore, the surgeon should defer any firm commitment to resection (e.g., dividing the blood supply) until resectability is confirmed.

Dissect the gallbladder off the gallbladder fossa, taking care to leave the cystic plate on the liver. The gallbladder can be left attached to the CBD and used as a retractor. Follow the cystic plate down to the hilar plate and lower the hilar plate by dividing its attachment to segment 4B all the way to the umbilical fissure. This allows palpation and inspection of the hilum to determine the extent of tumor involvement into the left and right hepatic ducts.

Dissection is then begun from below. Identify the common hepatic artery and the portal vein just above the neck of the pancreas and circumferentially clear these of all tissue. Continue the dissection proximally, retracting the hepatic artery to the left and the portal vein to the right. Adjacent areolar tissue, nerve trunks, and lymph nodes should be left in place around the CBD and the tumor [see Figure 10]. As noted, this approach differs from that used in resection of choledochal cysts [see Choledochal Cyst Resection, Operative Technique, above].

Step 2: Division of CBD

Once resectability is confirmed, divide the CBD at the level of the pancreas. Place a clamp on the end of the divided duct and use this as a retractor to facilitate the most proximal dissection of the CBD and the tumor away from the hepatic artery and the portal vein [see Figure 11].

Step 3: Proximal Dissection

With middle-third tumors or Bismuth type I proximal tumors, it is usually possible to palpate the proximal tumor margin and identify uninvolved right and left hepatic ducts. If this is not the case, the surgeon should consider the possibility of a type II or III tumor and be prepared to completely excise the bifurcation, with or without part of the liver.

Dissect the hepatic artery by retracting the vessel anteriorly and to the left, dividing and ligating the cystic artery where it originates from the right hepatic artery, and clearing all tissue off the right and left branches at least 1 cm proximal to the proximal margin of the tumor. Involvement of the right or left hepatic artery by tumor is a sign of extensive spread on the corresponding side and an indication for resection of that half of the liver.

Dissect the portal vein by retracting the bile duct and the tumor anteriorly and the hepatic artery to the left. All tissue should be cleanly dissected away from the portal vein to expose the bifurcation and the region proximal to it [see Figure 11]. At this point, the duct may be tethered down to the caudate lobe. Bile ducts from the caudate lobe may drain into the right or left duct and tumor may extend along these caudate ducts. Therefore, whether or not there is gross tumor in this area, the caudate lobe should be included in the resection.¹⁶

The level at which the proximal bile ducts are transected depends on the proximal extent of the tumor. For all middle-third or proximal tumors that are at least 1 cm beyond the bifurcation, proximal resection should be above the level of the bifurcation. For type I or type II proximal tumors, proximal resection should always include all of the bifurcation along with the proximal right and left bile ducts out as far as

Figure 10 Resection of middle-third and proximal bile duct tumors. Shown is the proper plane of dissection in the removal of a bile duct cancer. Except for the hepatic artery and the portal vein, all tissue stays with the common bile duct to be resected.

the first major branch [see Figure 12]. With type III or IV proximal tumors, the proximal extent of the tumor cannot be determined in both right and left ducts unless the main pedicles are dissected out of the liver. Because these tumors tend to infiltrate locally, such dissection is not advisable. Instead, concurrent hepatectomy should be performed to optimize the likelihood of curative resection. Intraoperative ultrasonography may help verify the extent of tumor at this point in the operation. Any major liver resection for type III

or IV bile duct cancer should include the caudate lobe [see Figure 13].

Before committing to a major hepatectomy (i.e., before dividing the blood supply), the tumor must be dissected away from the hepatic artery and portal vein branch supplying the segments of the liver to be preserved. Once this has been accomplished, the hepatic artery and the portal vein branch to the side to be resected can be divided. This allows the tumor to be retracted further and provides better exposure of the duct to the side to be preserved [see Figure 14 and Figure 15]. In selected cases, resection of an involved portal vein bifurcation may be carried out at this point [see Figure 16]; an end-to-end primary venorrhaphy (without the need for an interposition conduit) can usually be fashioned.

Figure 11 Resection of middle-third and proximal bile duct tumors. When resectability is confirmed, the common bile duct (CBD) is transected at the duodenum. The proximal portion of the divided duct is retracted anteriorly, and the CBD is cleaned off the portal vein up to a point above the bifurcation.

Figure 12 Resection of middle-third and proximal bile duct tumors. Illustrated is the level of resection for middle-third and type I proximal tumors. The common bile duct is resected from the pancreas to a point above the bifurcation. Reconstruction is accomplished via Roux-en-Y hepaticojejunostomy (involving either one or two separate anastomoses).

Figure 13 Resection of middle-third and proximal bile duct tumors. Illustrated are (a) a right trisectionectomy (extended right hepatectomy) for type II, IIIa, and IV tumors and (b) a left hepatectomy (including the caudate lobe) for type IIIb tumors.

The point at which the hepatic parenchyma will be divided is marked, and the parenchymal transection is performed. Division of the hepatic duct (or ducts) to the part of the liver being preserved is done as far from the tumor as possible.

Step 4: Reconstruction

After resection of the bifurcation or intrahepatic bile ducts, an intrahepatic cholangiojejunostomy is performed. The duct tissue is usually healthy enough and the duct lumen large enough to allow mucosa-to-mucosa repair without stenting.

Step 5: Closure and Postoperative Care

Close the abdomen in the standard fashion and place closed suction drains. In the early postoperative period, particularly when a major liver resection has been performed, mild abnormalities in coagulation test results are common. In the absence of active bleeding or severe coagulopathy, we do not administer fresh frozen plasma. Drains are removed 2 to 3 days postoperatively if there is no evidence of a bile leak.

COMPLICATIONS

Bile leakage, bleeding, and infection are the most important complications of bile duct resection for tumor. Following major hepatectomy, expect a transient rise in liver function

studies. A moderate increase in coagulation studies is also common, and we do not transfuse fresh frozen plasma for an international normalized ratio of 2.0 or less unless clinical bleeding is evident. Nevertheless, these laboratory values should be monitored closely in the early postoperative period as persistent elevation of liver function tests or coagulation studies is an indication of hepatic insufficiency. Parahepatic collections are treated with percutaneous drainage, and significant early postoperative bleeding is usually best managed by reexploration.

Repair of Biliary Injuries

Biliary injuries during laparoscopic cholecystectomy are estimated to occur in only 0.4 to 0.6% of cases, but with approximately 500,000 procedures yearly in the United States, this seemingly low injury rate translates into significantly increased cost, resource use, morbidity, and mortality.^{17–21} In as many as 50% of cases, the injury may be discovered at the time of operation, and depending on the type of injury, the surgeon may attempt an immediate repair.^{22,23} General surgeons who perform laparoscopic cholecystectomies should be adequately trained to repair Strasberg type A and D injuries [see Figure 17]. Strasberg type A injuries include cystic duct stump leaks or leakage from small ducts in the liver bed (e.g., duct of Luschka). If a type A injury is detected during laparoscopic cholecystectomy, oversew the offending duct (laparoscopically or open) and place a drain. A type D injury is a lateral injury to a major duct. One may safely perform a primary repair of the duct at the time of operation under the following conditions: (1) less than 25% of the circumference of the duct is involved, (2) the injury is not thermal (i.e., from a cautery burn), and (3) the duct is of sufficient caliber to allow insertion of a T tube. Place a T tube across the injury (via a separate incision in the duct) and perform a primary repair using fine absorbable monofilament suture. If any one of the above conditions is absent, the surgeon should instead perform a choledochojejunostomy as previously described or refer the patient to a hepatobiliary surgeon if necessary. Type B injuries usually involve ligation of an aberrant right hepatic duct and are rarely detected at the time of surgery. Type C injuries involve transection, but not ligation, of an aberrant (usually right hepatic) duct. If discovered at the time of operation, such injuries are best repaired immediately with cholangiojejunostomy. Strasberg type E injuries parallel the Bismuth classification system of biliary strictures. These injuries occur higher on the biliary tree, may be very complex, and are often accompanied by a vascular component. When such injuries are noted at the time of cholecystectomy, the surgeon must honestly assess his or her expertise in the repair of complex biliary injuries and do nothing that might worsen the injury. In general, this means that once any hemorrhage is carefully controlled, a drain should be placed, the wound should be closed, and the patient should be transferred without delay to the nearest specialty center with provider teams experienced in the management of complex biliary injuries.²⁴

Injuries not discovered at the time of initial operation may present days, weeks, or even years later.^{25,26} Signs and symptoms of delayed presentation vary depending on the nature of the injury and whether obstruction or bile leakage

Figure 14 Resection of middle-third and proximal bile duct tumors. Shown is the resection of type IIIb proximal tumors. (a) The common bile duct is retracted upward and to the left; the left hepatic artery is divided; and the right portal vein and the right hepatic artery, which are to be saved, are exposed. (b) The left portal vein is divided.

is the dominant pathology at the time. Persistent but usually mild, unexplained pain and malaise in the postoperative period are the most common initial symptoms, and the non-specific nature of these symptoms may lead to further delay in diagnosis.²⁷ Patients may also present with nausea, anorexia, elevated white blood cell count and liver function studies, fever, jaundice, cholangitis, or sepsis. Initial management depends on the clinical state of the patient. Correct any fluid and electrolyte derangements, administer appropriate analgesia to control the pain associated with bile peritonitis, and initiate broad-spectrum antibiotic coverage in any patient with infection. High-quality cross-sectional imaging—multi-phase CT, MRI/MRCP, or both—is essential to evaluate the extent of injury and detect abdominal fluid collections or major vascular injury. Patients with signs or symptoms of cholangitis or sepsis should undergo percutaneous drainage of any biloma or abscess seen on imaging, followed by PTC with placement of an external biliary drainage catheter (or bilateral catheters for type E4 injuries). No attempt should be made to internalize the biliary drainage catheter(s) until the patient becomes clinically stable.²⁸ Stable patients with jaundice and/or biloma may also undergo ERCP, and if a type A injury is clearly demonstrated, then drainage of the biloma and temporary biliary stenting until the leak ceases will usually solve the problem. To adequately define anatomy and plan repair of most other injuries, specifically those

involving excluded ducts, requires imaging of both the upper and lower bile ducts with both ERCP and PTC. Failure to adequately define the biliary anatomy and extent of injury by cholangiography predicts eventual failure of any repair.²⁴ Although there is no level 1 evidence to guide the timing of repair, we generally complete the necessary perioperative imaging studies and repair injuries within 24 hours of transfer under the following conditions: (1) the transfer occurs within 0 to 3 days of the injury, (2) peritoneal contamination is minimal and well drained, (3) the patient has no signs or symptoms of cholangitis or sepsis, and (4) there is no radiographic evidence of major vascular injury. Patients with bile peritonitis, abscesses, and cholangitis are managed as described above, and definitive repair is delayed for at least 3 months. Likewise, repair is delayed 3 months in patients with major vascular injuries to better establish the level of associated ductal ischemia and resulting stricture.

OPERATIVE TECHNIQUE

Step 1: Exposure of the Porta Hepatis

In patients who have sustained a biliary injury, particularly those who have already undergone attempted repair, local inflammation may obliterate the normal tissue planes and lead to significant distortions of the normal portal anatomy. The following are some useful techniques for safely

Figure 15 Resection of middle-third and proximal bile duct tumors. Shown is the resection of type II, IIIa, and IV proximal tumors. (a) The CBD is retracted upward and to the right; the right hepatic artery is divided; and the left portal vein and the left hepatic artery, which are to be saved, are exposed. (b) The right portal vein is divided.

defining the anatomy and avoiding potentially devascularizing dissection within the porta hepatis.

1. Use the round ligament to find the true porta hepatis. Patients who have already undergone one or more operations on the bile duct often have adhesions between the hepatoduodenal ligament and segment 4 of the liver. If one dissects this area via the anterior approach, one may think that the actual porta hepatis has been reached but notice that the hepatoduodenal ligament appears unusually short. In most cases, one can safely find the true porta by tracing the round ligament to the point where it joins the left portal pedicle and the umbilical portion (or ascending branch) of the left portal vein. To completely expose the umbilical fissure, the bridge of liver tissue between segment 4b and the left lateral section must first be divided. This tissue is devoid of any major vascular or biliary structures and may be safely divided with electrocautery. One may then follow the pedicle toward the right along the true porta. The adhesions between the hepatoduodenal ligament and segment 4b are more easily divided from the left than from the front.

2. Use aids to dissection. Usually, structures in the hepatoduodenal ligament can be identified by inspection and palpation, especially if a biliary stent is in place. When repairing complex, high biliary injuries (e.g., types E4 and E5), we routinely place percutaneous stents preoperatively for this purpose. Intraoperative Doppler ultrasonography may be useful in identifying the hepatic artery and the portal vein. Intraoperative ultrasonography may also be helpful in identifying the bile duct, and needle aspiration may be used before the duct is incised if there is any doubt about its location. Either blunt or sharp dissection is effective in this area. Our preference is to use a long fine right-angle clamp to obtain exposure in a layer-by-layer fashion. We then carefully cauterize or ligate and divide the exposed tissue.

Step 2: Defining the Duct

Carefully débride crushed, cauterized, or devitalized tissue back to normal healthy tissue. When performing a delayed repair, it is not necessary to resect all scar tissue around the duct. Just be certain that the anastomosis is constructed to healthy duct mucosa proximal to the injury and not to granulation tissue at the opening in the duct.

Figure 16 Resection of middle-third and proximal bile duct tumors. (a) Occasionally, a type III or IV proximal tumor will involve the portal vein bifurcation. (b) Shown is the resection of an involved portal vein bifurcation. Reconstruction is accomplished in an end-to-end fashion.

Step 3: Anastomosis

For all types of repair, construct a Roux-en-Y loop of sufficient length to make a tension-free anastomosis and perform a biliary-enteric anastomosis as previously described.

INJURY-SPECIFIC REPAIRS

E1- and E2-Type Injuries

Make a longitudinal incision in the anterior portion of the exposed duct and perform a vertical side-to-side anastomosis.

E3-Type Injuries

It is very rare for the left duct to be injured during a laparoscopic cholecystectomy; therefore, the left duct is also

less involved in the ensuing inflammatory processes that affect the common and right hepatic ducts. The surgeon can take advantage of this fact when repairing an E3-type injury. This injury is at the level of the confluence, but the confluence remains intact, and drainage of the left hepatic duct alone is sufficient to establish drainage for the entire liver. Using the techniques described above, identify and expose the extrahepatic left duct at the base of segment 4, make a longitudinal incision in the duct, and perform a transverse side-to-side bilioenteric anastomosis [see Figure 18]. This technique,

Figure 17 Strasberg classification of biliary injuries.

Figure 18 Hepp-Couinaud approach to repair of a Type E3 bile duct injury.

described by Hepp and Couinaud in 1956,²⁹ is known as the Hepp-Couinaud technique. We recently published our experience with this technique, which provides excellent long-term results.³⁰

E4- and E5-Type Injuries

In these types of injuries, all (E4) or some portion (E5) of the right ductal system is isolated from the left ductal system. Therefore, the Hepp-Couinaud approach provides adequate drainage only for those segments of liver with bile ducts in continuity with the left hepatic duct. The excluded right side must be drained separately, but inflammation and scar tissue make exposing the right duct more challenging. Rather than attempting to dissect out the right duct directly, begin the dissection along the left hepatic duct and under the base of

segment 4, rolling the base of segment 4 upward (lowering the hilar plate). The takeoff of the right duct is located within the same coronal plane as the left duct, so keep the dissection in this same plane, continuing to the right until encountering the attachment of the cystic plate to the right portal pedicle. Divide this fibrous tissue band and then elevate and dissect the liver at the base of segment 5, exposing the sheath of the right portal pedicle. Palpate the previously placed stent to confirm the position of the right bile duct within the sheath. Intrahepatic exposure of the right pedicle is usually possible and a well-vascularized, uninjured duct can be identified for anastomosis. In extremely rare cases of very proximal right-sided injuries, hepatic resection may be required.³¹

23 HEPATIC RESECTION

*Clifford S. Cho, MD, and Yuman Fong, MD, FACS**

Although first described centuries ago, the majority of liver resections were performed for management of trauma or infection until the latter half of the 20th century. Today, partial hepatectomy is performed not only for treatment of acute emergencies but also as potentially curative therapy for a variety of benign and malignant hepatic lesions.^{1–5}

The first planned anatomic resection of a lobe of a liver is credited to Lortat-Jacob, who performed a right hepatic lobectomy in 1952 as treatment for metastatic colon cancer.⁶ However, it was not until the 1980s that major hepatectomies became commonplace. Since that time, the safety of hepatic resection has improved dramatically; moreover, as the safety of the operation has improved, the indications for hepatic resection have broadened. Currently, resection of as much as 85% of functional liver parenchyma is being performed at numerous centers with an operative mortality of less than 2%. The duration of hospitalization is typically well less than 2 weeks, and nearly all patients regain normal hepatic function postoperatively.⁷

In this chapter, we focus on the technical aspects of hepatic resection, emphasizing efficiency and safety and taking into account recent developments, current controversies, and special operative considerations (e.g., the cirrhotic patient and repeat liver resection). Detailed discussions of the indications for hepatic resection are available elsewhere.^{8–10}

Hepatic Anatomy

Safe operative conduct during partial hepatectomy demands a close familiarity with the surgical anatomy of the liver.¹¹ In 1998, in response to the confusion created by various anatomic nomenclatures applied to the liver, the International Hepato-Pancreato-Biliary Association (IHPBA) appointed a committee charged with establishing a universal terminology for hepatic anatomy and hepatic resections. In 2000, the recommendations of this committee were accepted at IHPBA's biannual meeting in Brisbane. Accordingly, this system for naming the anatomic divisions of the liver and their corresponding resections has come to be known as the Brisbane 2000 terminology.¹²

In the Brisbane 2000 system, the anatomy of the liver may be thought of in terms of first-order, second-order, and third-order divisions, all of which are based on the underlying vascular and biliary anatomy and not on surface features [see Figure 1]. At the first level, the liver is divided into two hemilivers (right and left). At the second level, it is divided into four sections (right posterior, right anterior, left medial, and left lateral). At the third level, it is divided into nine

segments, each of which is a discrete anatomic unit that possesses its own nutrient blood supply and venous and biliary drainage.

The right hemiliver consists of segments V through VIII and is nourished by the right hepatic artery and the right portal vein; the left hemiliver consists of segments II through IV and is nourished by the left hepatic artery and the left portal vein. (The caudate lobe, a portion of the liver that is separate from the two hemilivers, consists of segments I and IX.) The anatomic division between the right hemiliver and the left hemiliver is not at the falciform ligament (the most readily apparent visual landmark on the anterior liver) but follows the principal scissura (or Cantlie line) that runs posterosuperiorly from the medial margin of the gallbladder to the left side of the inferior vena cava.

The venous drainage of the liver consists of multiple small veins draining directly from the back of the right hemiliver and the caudate lobe to the inferior vena cava, along with three major hepatic veins. These major hepatic veins occupy three planes, known as portal scissurae. The three scissurae divide the liver into the four sections, each of which is supplied by a portal pedicle; further branching of the pedicles subdivides the sections into their constituent segments. The right hepatic vein passes between the right anterior section (segments V and VIII) and the right posterior section (segments VI and VII) in the right scissura. This vein empties directly into the vena cava near the atriocaval junction. The middle hepatic vein passes between the right anterior section and the left medial section (segment IV, sometimes subdivided into segments IVa and IVb) in the principal scissura that divides the right and left hemilivers. The left hepatic vein runs in the left scissura between segments II and III (which together comprise the left lateral section). In most persons, the left and middle hepatic veins join to form a common trunk before entering the inferior vena cava. Occasionally, a large inferior right hepatic vein is present that can provide adequate drainage of the right hemiliver after resection of the left even when all three major hepatic veins are ligated.¹³

The portal vein and hepatic artery divide into left and right branches below the hilum of the liver. Unlike the major hepatic veins, which run between segments, the portal venous and hepatic arterial branches, along with the hepatic ducts, typically run centrally within segments [see Figure 1]. On the right side, the hepatic artery and the portal vein enter the liver substance almost immediately after branching. The short course of the right-sided extrahepatic vessels and the variable anatomy of the biliary tree make these vessels vulnerable to damage during dissection.¹⁴ In contrast, the left branch of the portal vein and the left hepatic duct take a long extrahepatic course after branching beneath the undersurface of segment IV. When these vessels reach the base of the umbilical fissure, they are joined by the left hepatic artery to form a triad, which

* The authors and editors gratefully acknowledge the contributions of the previous author, James Park, MD, to the development and writing of this chapter.

Figure 1 The liver is separated into nine anatomic segments, each with an independent nutrient blood supply and venous and biliary drainage. Appreciation of this segmental anatomy is the basis of anatomic resection of the liver.

then enters the substance of the left hemiliver. Importantly, the left-sided structures are not a triad proximal to the base of the umbilical fissure. This long extrahepatic course makes operative exposure of the left-sided structures far easier than on the right. A surgical consequence of this anatomy is that when a choice exists between extended right hepatectomy and extended left hepatectomy [see Operative Technique, *below*] for resection of tumors involving the hepatic hilum (e.g., Klatskin tumors), most surgeons choose the former because of the greater ease of dissection and preservation of the left-sided structures. Knowledge of the relative anatomic courses of the portal veins, hepatic arteries, and hepatic ducts is the basis of the classic extrahepatic dissection for control of hepatic inflow [see Operative Technique, Right Hepatectomy, Step 6 (Extrahepatic Dissection and Ligation): Control of Inflow Vessels, *below*].

The fibrous capsule surrounding the liver substance was described by Glisson in 1654.¹⁵ It was Couinaud, however, who demonstrated that this fibrous capsule extends to envelop the portal triads as they pass into the liver substance.¹⁶ Thus, within the liver parenchyma, the portal vein, hepatic artery, and hepatic duct running to each segment of the liver lie within a substantive sheath. This dense sheath facilitates rapid control of inflow vessels to specific anatomic units

within the liver and permits en masse ligation of these vascular structures in a maneuver known as pedicle ligation [see Operative Technique, Right Hepatectomy, Step 6—Alternative (Intrahepatic Pedicle Ligation): Control of Inflow Vessels, *below*].¹⁷

Preoperative Evaluation

Cross-sectional imaging modalities such as computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography play important roles in enhancing the safety and efficacy of hepatic resection. These modalities, along with biologic scanning techniques such as positron emission tomography (PET), are also invaluable for staging malignancies so as to improve patient selection and thereby optimize long-term surgical outcomes.³

At a minimum, all candidates for hepatic resection should undergo either CT or MRI. These imaging tests not only identify the number and size of mass lesions within the liver but also delineate the relationships of the lesions to the major vasculature—data that are crucial for deciding whether to operate and which operative approach to employ.

Use of contrast enhancement during CT scanning is vital for accurate definition of the vascular anatomy. Data from

thin-slice (1 to 2 mm) images captured by current spiral (helical) CT scanners can be reconstructed to provide angiographic images whose level of detail rivals that of direct angiograms [see Figure 2]. Triple-phase scans (including a noncontrast phase, an arterial phase, and a venous phase) are recommended as these permit optimal definition and characterization of intrahepatic lesions. For example, some vascular tumors become isodense with liver parenchyma after contrast injection. By first obtaining noncontrast scans and then obtaining contrast scans at two different times after contrast injection, the likelihood of detecting such tumors is enhanced.

For small tumors, CT portography may be employed. In this technique, contrast material is injected through the superior mesenteric artery, and images are obtained during the portal venous phase. The normal liver receives the majority of its nutrient blood from the portal vein and is therefore contrast enhanced in this phase. Tumors, on the other hand, usually derive their nutrient blood from the hepatic artery and therefore appear as exaggerated perfusion defects. For this reason, CT portography is highly sensitive for identifying small hepatic tumors.¹⁸

MRI may also be valuable for characterizing lesions and defining their relationships with the vasculature. It is particularly helpful in diagnosing benign lesions such as hemangioma, focal nodular hyperplasia, and adenoma. Whenever any of these benign lesions is suspected, MRI is typically indicated. With regard to surgical planning, magnetic resonance angiography is useful for identifying the major hepatic veins and clarifying their relationship to tumors.¹⁹

Over the past decade, biologic imaging in the form of ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET), has emerged as an invaluable technique for preoperative staging of patients with hepatic malignancies. In patients with hepatic metastases being considered for resection, FDG-PET can identify occult foci of disease not detected by other modalities that may represent contraindications to operative

intervention. In this way, incorporation of FDG-PET into the diagnostic regimen of these patients can decrease the incidence of nontherapeutic laparotomy²⁰ and improve long-term survival among cases where resection is indicated.²¹ Of note, the role of FDG-PET in the evaluation of patients with primary hepatocellular carcinoma (HCC) is less clear in that many HCC tumors cannot be distinguished from the surrounding liver through assessment of glucose metabolism alone.

To summarize imaging recommendations, a triple-phase CT scan should be obtained for most patients being considered for hepatic resection. If diagnostic doubt remains after CT, particularly if the differential diagnosis includes an asymptomatic benign tumor, MRI should be performed. If questions remain after CT as to the extent of hepatic venous or major biliary involvement, MRI or duplex ultrasonography should be considered.²² If small tumors are encountered, CT portography may be helpful for further characterization. By demonstrating the vascular hilar structures, hepatic veins, and inferior vena cava, duplex ultrasonography obviates the need for angiography in many cases.^{19,23} For patients with liver metastases from colorectal cancer,⁴ breast cancer, or melanoma, FDG-PET imaging should be performed before hepatic resection. Direct hepatic angiography is rarely required, and inferior vena cavography is almost never necessary.

Operative Planning

PREPARATION

In general, preparation for hepatic resection is similar to preparation for any other major abdominal procedure. Patients with a history of cardiopulmonary disease undergo a full cardiopulmonary assessment. It was once believed that patients over the age of 70 years were poor candidates for major liver resection,^{24,25} but this notion has been dispelled by

Figure 2 (a) The arterial anatomy of the celiac axis is reconstructed from thin-slice computed tomographic images. (b) The hepatic venous anatomy is similarly reconstructed, with the tumor superimposed on the vascular reconstruction.

more recent data^{26–28}; advanced chronologic age is not an absolute contraindication to partial hepatectomy.

If present, anemia and coagulopathy are corrected in the preoperative period. If feasible, patients may be encouraged to donate two units of autologous blood before undergoing major partial hepatectomy. Alternatively, hemodilution, in which a portion of the patient's blood volume is withdrawn intraoperatively and reinfused immediately after the completion of the hepatectomy, may be considered.

Appropriate single-dose antibiotic prophylaxis is administered in the immediate preoperative period.

ANESTHESIA

Considerations regarding anesthesia should account for the possibilities of baseline hepatic dysfunction from underlying liver disease, as well as postoperative hepatic dysfunction resulting from resection of large portions of hepatic parenchyma. The most important consideration, however, is the possibility of major intraoperative hemorrhage. Suitable hemodynamic monitoring and sufficient vascular access to permit rapid transfusion must be established prior to liver resection. In the past, fluid resuscitation and blood transfusions were often initiated early in the course of resection to increase intravascular volume as a buffer against sudden blood loss. The opposite approach is currently favored, in which a low central venous pressure is intentionally maintained before and during hepatic parenchymal transection. The rationale for this approach is that most hemorrhage encountered during hepatic resection is a result of venous back-bleeding from major hepatic veins or the inferior vena cava.^{29,30} Maintenance of central venous pressures below 5 mm Hg combined with elevation of liver tissue results in less back-bleeding from the hepatic venous radicles during dissection. Reduction of intrahepatic venous pressure can be facilitated by placing the patient in a 15° Trendelenburg position, which increases venous return to the heart and enhances cardiac output. Central venous pressure is maintained at the desired level through a combination of anesthesia and early intraoperative fluid restriction.

The need for intraoperative blood transfusion can be minimized by accepting hematocrit levels of 24% in patients without antecedent cardiac disease and 29% in patients with significant cardiac disease. If blood loss is estimated to reach or exceed 20% of total volume, or if the patient becomes hemodynamically unstable, transfusion is warranted.^{29,30}

PATIENT POSITIONING

The patient should be placed in a supine position; even for patients with very large tumors, we have not found a left lateral decubitus position to be necessary. Electrocardiographic leads should be kept clear of the right chest wall and the presternal area in the event that a thoracoabdominal incision becomes necessary because of difficulties with liver mobilization or intraoperative hemorrhage. Preparation and draping should therefore also allow for satisfactory exposure of the lower chest and the entire upper abdomen down past the umbilicus. A crossbar or a similar device that holds self-retaining retractors should be used to elevate the costal margin in an anterosuperior direction. Ring-based self-retaining retractors are also adequate for most resections; however, particularly in large patients, the rings can restrict

lateral access during posterior dissection, particularly when mobilizing the right hemiliver off the diaphragm and inferior vena cava.

ANATOMIC VERSUS NONANATOMIC RESECTION

A key decision when planning partial hepatectomy is whether to undertake an anatomic or nonanatomic resection. In the treatment of malignant disease, anatomic resection is generally favored as the long-term outcome appears to be improved. Anatomic resections result in the excision of parenchymal areas distal to the index tumors, where vascular micrometastases may reside. In addition, they are significantly less likely to result in positive resection margins. In a large series of partial hepatectomies performed for metastatic colorectal cancer, wedge or nonanatomic resections were associated with a 19% rate of positive margins.³¹ In another analysis, wedge resections were associated with a 16% rate of positive margins compared with a 2% rate seen with anatomic resections.³²

Importantly, there are two oncologic settings in which nonanatomic resections are favored. In patients with HCC, viral hepatitis and cirrhosis are often complicating underlying factors. Cirrhotic patients do not tolerate resection of more than two segments of functional parenchyma well; for these patients, the smallest resection that will achieve complete tumor excision is favored even if it involves a nonanatomic wedge resection. In patients with hepatic neuroendocrine metastases, for whom resections are cytoreductive procedures often designed to alleviate symptoms, nonanatomic resections are acceptable because the likelihood of cure is very small.³³

Hepatic resections for benign tumors are usually performed for one of three reasons: (1) symptom alleviation (e.g., pain or early satiety), (2) diagnostic uncertainty, or (3) prevention of malignant transformation.³⁴ One goal of these resections should be to spare as much normal parenchyma as possible. Consequently, lesions such as hemangiomas, adenomas, complex cysts, and focal nodular hyperplasia are commonly excised by means of enucleation or other nonanatomic resections with limited margins.

Operative Technique

In theory, any hepatic segment may be resected in isolation. For practical purposes, however, there are six major types of anatomic resection. As stated earlier, we employ the Brisbane 2000 terminology for hepatic resection [see *Figure 3*].

The core principles of all anatomic hepatic resections are the same: (1) control of inflow vessels, (2) control of outflow vessels, and (3) parenchymal transection. To illustrate these principles, we begin by outlining the steps involved in right hepatectomy [see *Figure 3a*] in some detail, describing both extrahepatic vascular dissection and ligation and the alternative intrahepatic pedicle ligation approach to inflow control. Left hepatectomy [see *Figure 3b*] and other common anatomic resections [see *Figure 3, c, d, e, f*] share a number of steps in common with right hepatectomy; accordingly, we discuss them in less detail. Further detail on these procedures is available in other sources.^{35,36}

Figure 3 Shown are schematic illustrations of standard hepatic resections, with the shaded areas representing the resected portions: (a) right hepatectomy, (b) left hepatectomy, (c) right trisectionectomy (extended right hepatectomy), (d) left lateral sectionectomy, (e) left trisectionectomy (extended left hepatectomy), and (f) right posterior sectionectomy.

RIGHT HEPATECTOMY (RIGHT HEMIHEPATECTOMY)

Step 1: Laparoscopic Inspection

Laparoscopic examination of the peritoneal cavity can detect unresectable metastases that cannot be visualized by cross-sectional imaging, thereby preventing the morbidity associated with a nontherapeutic laparotomy.^{37–40} We generally perform laparoscopy immediately before laparotomy during the same period of anesthesia. The laparoscopic port sites are placed in the upper abdomen along the line of the intended incision [see Step 2, below]. The first two ports are usually 5 or 10 mm ports placed in the right subcostal area along the midclavicular line and along the anterior axillary line. These ports allow inspection of the abdomen and of the entire liver, including the dome and segment VII. A 10 mm port along the right anterior axillary line is particularly suitable for laparoscopic ultrasound devices. If additional ports are necessary, a left subcostal midclavicular port is usually the best choice.

Step 2: Incision

If no evidence of distant or unresectable metastasis is identified at the time of laparoscopy and an open hepatic resection is planned, an incision that will afford optimal exposure of the liver is made. For most hepatic resections, many surgeons use a bilateral subcostal incision extended vertically to the xiphisternum [see Figure 4]. Our preference is to use an upper midline incision extending to a point approximately 2 cm above the umbilicus, with a rightward extension to a point in the midaxillary line halfway between the right costal margin and the right anterior superior iliac spine [see

Figure 4]. This incision provides superb access for both right- and left-sided resections and avoids the wound complications often encountered with trifurcated incisions (e.g., ascites leak, incisional hernia). On rare occasions (e.g., resection of large and rigid posterior tumors of the right hemiliver), a right thoracoabdominal incision may be required. However, in a series of nearly 2,000 resections performed at Memorial Sloan-Kettering Cancer Center, a thoracoabdominal incision was necessary in only 3% of cases, with the most common indication being repeat liver resection after previous right hepatectomy [see Repeat Hepatic Resection, below].

Step 3: Abdominal Exploration and Intraoperative Ultrasonography

Exploration commences with bimanual palpation of the entire liver. Intraoperative ultrasonography (IOUS) is then performed systemically to identify all lesions and their relation to the major vascular structures. IOUS is capable of identifying small lesions that preoperative imaging studies and palpation of the liver may miss.⁴¹ The lesser omentum is incised to allow examination of the caudate lobe and inspection of the celiac axis nodal metastases. A finger is passed from the lesser sac inferior to the caudate lobe through the foramen of Winslow to permit identification of the portal vein and palpation of the portocaval lymph nodes. The hilar lymph nodes are palpated, and any suspicious nodes may be excised and submitted for frozen-section pathologic analysis. If the operation is being undertaken for malignancy, the entire abdomen is also inspected for evidence of extrahepatic tumors.

Figure 4 Right hepatectomy. A right subcostal incision (A) with a midline extension to the xiphoid (D) is the most common choice; an extension to the left subcostal area (C) is sometimes added to provide further operative exposure. We prefer a long midline incision from the xiphoid (D) to a point approximately 2 to 3 cm above the umbilicus (B) along with a rightward extension (A) because this incision provides superb exposure of both the right side and the left without the wound complications of a trifurcated incision. The chest can be entered through either a median sternotomy (E) or an anterolateral right thoracoabdominal incision (F).

Step 4: Mobilization of Liver

Once the decision is made to proceed with hepatic resection, the liver is fully mobilized by detaching all ligamentous attachments on the side to be resected. (Some surgeons defer completion of mobilization to a later stage in the procedure.) In particular, the falciform ligament is divided and the suprahepatic inferior vena cava and the hepatic veins above the liver are dissected to facilitate the subsequent approach to the hepatic veins [see Step 7: Control of Outflow Vessels, below]. Early mobilization of the liver will facilitate additional bimanual palpation to detect small lesions that may have been obscured during the initial examination. This additional palpation is particularly important on the right side as the right posterior section cannot be effectively examined prior to mobilization, and IIOUS may fail to detect small lesions in this area.⁴¹

During the course of mobilization, if tumor is found to be attached to the diaphragm, the affected area of diaphragm may be excised and subsequently repaired.

Step 5: Identification of Arterial Anomalies

The presence of possible hepatic arterial anomalies should be verified before resection is initiated. With contemporary

imaging techniques, the arterial anatomy can usually be defined with sufficient exactitude prior to laparotomy. However, it is also possible to clarify the arterial anatomy intraoperatively with several simple maneuvers that do not involve major dissection.

The lesser omentum should be examined to determine whether there is a vessel coursing through its middle to the base of the umbilical fissure, and the hepatoduodenal ligament should be palpated with an index finger within the foramen of Winslow to determine whether there is an artery in the gastropancreatic fold along its medial aspect. The usual bifurcation of the hepatic arteries occurs low and medially within the hepatoduodenal ligament, and the left hepatic artery normally travels on the medial aspect of the ligament to reach the base of the umbilical fissure. Therefore, an artery palpable in the medial upper portion of the hepatoduodenal ligament is the main left hepatic artery. If the main left hepatic artery is identified in this manner, any vessel identified in the lesser omentum must be an accessory left artery. If no arterial structure is found in the medial upper portion of the hepatoduodenal ligament, the vessel in the lesser omentum must be a replaced left hepatic artery. The right hepatic artery typically travels transversely behind the common bile duct (CBD) to reach the base of the cystic plate. An artery traversing vertically along the lateral hepatoduodenal ligament must therefore be either a replaced or an accessory right hepatic artery, likely arising from the superior mesenteric artery.

Step 6 (Extrahepatic Dissection and Ligation): Control of Inflow Vessels

The classic approach to controlling the inflow vessels during right hepatectomy involves extrahepatic dissection and ligation [see Figure 5]. The cystic duct and the cystic artery are ligated and divided. The gallbladder may be either removed or left attached to the right hemiliver, according to the surgeon's preference. A common practice is to first ligate the right hepatic duct, then the right hepatic artery, and finally the right portal vein, working from anterior to posterior. However, our preference is to work from posterior to anterior.

The sheath of the porta hepatis is opened laterally. Dissection is performed in the plane between the CBD and the portal vein. To facilitate this dissection, the CBD is elevated by applying anterior traction to the ligated cystic duct. The portal vein is followed in a cephalad direction until its bifurcation into the left and right portal veins is visible. Visualization of this bifurcation is critical because the left portal vein arises from the right anterior branch of the portal vein in a small percentage of patients. If the main right portal vein is ligated in a patient with this anatomic variant, portal flow to the entire liver, including the remnant left hemiliver, will be lost. There is usually a small portal branch that passes from the main right portal vein to the caudate process; ligation of this branch will untether an additional 1 to 2 cm of the right portal vein, allowing safer dissection and ligation. The right portal vein can be occluded with vascular clamps, divided, and oversewn with nonabsorbable sutures. Once divided, the right hepatic artery becomes readily visible behind the CBD and can be easily secured and ligated with nonabsorbable sutures. Because of the multitude of biliary anatomic variations, we typically leave the right hepatic duct intact until

Figure 5 Right hepatectomy. For control of the inflow vessels of the right hemiliver, the liver is retracted cephalad to allow exposure of the porta hepatis. (a) The gallbladder is resected to allow access to the bile duct and hepatic vessels. (b) The right hepatic duct is ligated to allow access to the hepatic artery and the portal vein. (c) After the right hepatic artery is divided, the right portal vein is controlled and divided. Alternatively, the vessels may be approached from a posterolateral direction and the portal vein and hepatic artery may be divided first, with the hepatic duct left intact until the parenchymal transection.

parenchymal dissection [see Step 8: Parenchymal Dissection, below] is begun; this structure can then be divided higher within the hepatic parenchyma to minimize the likelihood of injury to the left ductal system. Once the portal vein and hepatic artery are divided, a clear line of ischemic demarcation of the right hemiliver will be visible along the Cantlie line.

Staple ligation Alternatively, vascular staplers may be used to divide the right or the left portal vein during extrahepatic vascular dissection^{42,43}; in most cases, suture ligation of the extrahepatic portal veins is such a straightforward technical exercise that staplers add little except cost.

Step 6—Alternative (Intrahepatic Pedicle Ligation): Control of Inflow Vessels

As stated above, Glisson and Couinaud observed that the nutrient vessels to the liver are contained within a thick connective tissue capsule [see Figure 6]; this was the basis for the initial proposal by Launois and Jamieson that intrahepatic vascular pedicle ligation could serve as an alternative to extrahepatic dissection and ligation for controlling vascular inflow to the liver.¹⁷ This alternative technique has the advantages of being rapid and less likely to cause injury to the vasculature or the biliary drainage of the contralateral liver. Using this technique, one can readily access and isolate the major pedicles to the areas of liver to be resected using simple combinations of hepatotomies at specific sites along the inferior surface of the liver [see Figure 7].

In this approach, the right hemiliver is completely mobilized from the retroperitoneum. The most inferior small hepatic veins are ligated, and the inferior right hemiliver is mobilized off the vena cava. Incisions are made in the liver capsule at hepatotomy sites A and B [see Figure 7]. The first incision is made through the caudate lobe. The full thickness of the caudate lobe is divided with a combination of diathermy, crushing, and ligation. The second incision is made almost vertically in the medial part of the gallbladder bed. Both incisions must be fairly substantive and reasonably deep. Care must be taken to avoid the terminal branches of the middle hepatic vein, particularly along hepatotomy site B, as this is the most common source of bleeding. Using either finger dissection or passage of a large curved clamp (e.g., a renal pedicle clamp), a tape is placed around the right main sheath [see Figure 8]. This tape can be pulled medially to provide better exposure of the intrahepatic right pedicle and to retract the left-sided structures away from the area to be clamped and divided. Vascular clamps are applied, the right pedicle is divided, and the stumps are suture-ligated.

In practice, for right hepatectomy, we prefer to isolate the right anterior and posterior pedicles separately [see Figure 8] and ligate them individually. By dividing the right inflow structures higher within the liver, this measure ensures that the left-sided structures cannot be injured. Any minor bleeding from a hepatotomy usually ceases spontaneously or with application of Surgicel into the wound.

Figure 6 Right hepatectomy. The Glisson sheath is a vascular and biliary pedicle that contains the portal triad. If this sheath is not violated, the entire pedicle can be suture-ligated or staple-ligated with confidence and safety.

Figure 7 Right hepatectomy. Depicted are sites where hepatotomies can be made to permit isolation of various vascular pedicles. Incisions at sites A and B allow isolation of the right main portal pedicle. Incisions at sites A and D allow isolation of the right posterior portal pedicle. Incisions at sites B and D allow isolation of the right anterior pedicle. Incisions at sites C and E allow isolation of the left main portal pedicle; if the caudate lobe is to be removed, incisions are made at sites C and F. The Roman numerals refer to the hepatic segments.

Figure 8 Right hepatectomy. Depicted is isolation of the main right portal pedicle. The pedicle is controlled with a vascular tape and retracted from within the liver substance. This tape can be used for countertraction when a vascular clamp or stapler is applied. The main right portal pedicle has anterior and posterior branches. The right anterior pedicle consists of pedicles to segments V and VIII. The right posterior pedicle usually consists of only the segment VI pedicle but may also give rise to the segment VII pedicle.

Staple ligation The use of staplers is now well established for liver resections^{42–47}; we have found that staple ligation greatly increases the speed with which intrahepatic portal pedicle ligations can be performed. To control the intrahepatic portal pedicles for a right hepatectomy, incisions are made at hepatotomy sites A and B [see Figure 7]. Ultrasonography directed from the inferior aspect of the liver helps determine the depth at which the right pedicle lies, which is usually 1 to 2 cm from the inferior surface. The right main pedicle is secured and encircled with an umbilical tape [see Figure 9a]. The hilar plate along the base of segment IV is lowered via an incision at hepatotomy site C [see Figure 7] to ensure that the left-sided vascular and biliary structures are mobilized well away from the area of staple ligation. A transverse anastomosis (TA) vascular stapler is applied to the right main pedicle while firm countertraction is applied to the umbilical tape to pull the hilum to the left [see Figure 9a]. The stapler is fired, and the pedicle is divided [see Figure 9b].

Troubleshooting Several important principles should be followed when considering intrahepatic pedicle ligation. The most important is that intrahepatic pedicle ligation should not be undertaken when resection is being performed for a tumor located within 2 cm of the hepatic hilum. In these cases, extrahepatic dissection should be performed to avoid potential violation of the tumor margin.

From a technical standpoint, removal of the gallbladder greatly facilitates isolation and control of right-sided vascular pedicles in a right hepatectomy. Application of the Pringle maneuver decreases bleeding during hepatotomy and isolation of the pedicle. Also, the lowest hepatic veins behind the liver should be dissected before any attempt is made to isolate the right-sided portal pedicles as incising the caudate lobe without first dividing the small hepatic veins draining this portion of the liver to the inferior vena cava can lead to troublesome hemorrhage.

Step 7: Control of Outflow Vessels

Control of the outflow vessels begins with division of the hepatic veins passing from the posterior aspect of the right hemiliver directly into the inferior vena cava. After the right hemiliver is completely mobilized off the retroperitoneum by dividing the right triangular ligament, it is carefully dissected off the vena cava. Dissection proceeds in a cephalad direction from the inferior border of the liver until the right hepatic vein is exposed. Complete mobilization of the right hemiliver is particularly critical for tumors close to the vena cava. Exposure of the right hepatic vein usually requires division of the inferior vena caval ligament, which connects the right hemiliver to the diaphragm along the right lateral aspect of the right hepatic vein. The right hepatic vein is then isolated, cross-clamped, divided, and oversewn [see Figure 10]. Unless the lesion to be resected involves the middle hepatic vein close to its junction with the vena cava, the middle hepatic vein usually is not controlled extrahepatically for right-sided resections and can be easily secured during parenchymal transection.

In cases where a large tumor resides at the dome of the liver, control of the hepatic veins and the vena cava may prove very difficult. In this circumstance, one should not hesitate to extend the incision into the chest with a right thoracoabdominal extension. The morbidity of a thoracoabdominal incision is preferable to the potentially catastrophic hemorrhage that may be encountered when the right hepatic vein is torn during mobilization of a rigid right hemiliver containing a bulky tumor.

Staple ligation Staple ligation has proven very useful for outflow control during partial hepatectomy. When the tumor is in proximity to the hepatic vein–inferior vena cava junction, extrahepatic control of the hepatic veins is essential for excision of the tumor with clear margins, and limits blood loss during parenchymal transection.⁴⁸ Ligation of the hepatic veins, particularly when an adjacent large and rigid tumor is

Figure 9 Right hepatectomy. Shown is staple ligation of the right portal pedicle. (a) After the liver is incised across the caudate lobe and along the gallbladder bed, the right main pedicle is isolated and held with an umbilical tape. Countertraction is placed on the umbilical tape while a transverse anastomosis vascular stapler is placed across the pedicle, allowing the left hepatic duct and the left vascular structures to be retracted away from the line of stapling. (b) After the stapler is fired, the pedicle is clamped and divided.

Figure 10 Right hepatectomy. Once the small perforating vessels to the vena cava have been ligated, further dissection cephalad leads to the right hepatic vein. This vessel is controlled with vascular clamps and divided.

present, can be a technically demanding and dangerous exercise. Tearing the hepatic vein or the inferior vena cava during this maneuver is the most common cause of major intraoperative hemorrhage.³⁶ The linear cutting stapler is well suited for ligation of the major hepatic veins because of its low profile and ability to seal the hepatic vein on the inferior vena cava and resection specimen sides simultaneously.

For staple ligation of the right hepatic vein, the right hemiliver is mobilized off the vena cava. Any large accessory right hepatic vein encountered can also be staple-ligated, as can the tongue of liver tissue that often passes from the right hemiliver behind the vena cava to the caudate lobe. The right hepatic vein is then identified and isolated. Although some surgeons introduce the stapler from the top of the liver downward,⁴³ we find that the location of the liver high in the surgical wound can make this angle of introduction difficult. Rather, we typically introduce the stapler parallel to the vena cava and direct it from below upward [see Figure 11]. To ensure that the stapler does not misfire, care should be taken to confirm that no vascular clips are present near the area where the stapler is to be applied.

Step 8: Parenchymal Transection

Inflow to the left hemiliver can be temporarily interrupted by clamping the hepatoduodenal ligament (the Pringle maneuver). The safety of temporary occlusion of the vessels supplying the hepatic remnant is well documented. Even in patients with cirrhosis, the warm ischemia produced by

Figure 11 Right hepatectomy. As an alternative to clamping and division, the right hepatic vein may be staple-ligated. Once the small perforating tributaries from the right hemiliver to the vena cava have been divided, the right hepatic vein is isolated and ligated with an endoscopic gastrointestinal anastomosis (GIA) vascular stapler. The safest method for introducing this stapler is to retract the liver cephalad and to the left while advancing the stapler cephalad in the direction of the vena cava.

continuous application of the Pringle maneuver is well tolerated for as long as 1 hour.⁴⁹ Our practice is to apply the Pringle maneuver intermittently for periods of 10 minutes, with 2 to 5 minutes of perfusion between applications to allow for intestinal venous decompression.

Parenchymal division is then initiated along the line demarcated by devascularization of the right hemiliver. The line of transection along the principal plane is marked with the electrocautery, and the Glisson capsule is cut with scissors. Stay sutures of 0 chromic catgut are placed on either side of the plane of transection and used for traction, separation, and elevation as dissection proceeds.

Many special instruments have been proposed for use in parenchymal transection, including electrocautery, ultrasonic dissectors, and water-jet dissectors. For the majority of hepatic resections, we find that blunt clamp dissection is the most rapid method and is quite safe. In this technique, a large Kelly clamp is used to crush the liver parenchyma [see Figure 12]. The relatively soft liver substance dissects away, leaving behind the vascular and biliary structures, which are then ligated with vascular clips. Using this technique, the principal plane of the liver can usually be transected in less than 30 minutes.

In cirrhotic patients, the clamp-crushing technique may not work well because the vessels will often tear before the firm liver parenchyma does. Accordingly, ultrasonic dissectors that coagulate while transecting the parenchyma may be a better choice for cirrhotic patients. Water-jet dissectors may be useful in defining the major intrahepatic vascular pedicles or the junction of the hepatic vein and the vena cava, particularly when the tumor is in close proximity.

After the specimen is removed, the raw surface of the hepatic remnant is carefully examined for hemostasis and bile leakage. Any oozing from the raw surface may be controlled with the argon beam coagulator. Bile leaks should be controlled with clips or suture ligation. The retroperitoneal

Figure 12 Right hepatectomy. The parenchyma can be quickly and safely transected by means of the clamp-crushing technique. Large vessels and biliary radicles are visualized and ligated or clipped. This is usually done in tandem with inflow occlusion (i.e., the Pringle maneuver). Alternatively, the parenchyma can be bluntly dissected away by means of the finger-fracture technique.

surfaces should be examined carefully for hemostasis, and the argon beam coagulator can be used where necessary.

Step 9: Closure and Drainage

The abdominal wall is closed in one or two layers with continuous absorbable monofilament sutures. The skin is closed with staples or subcuticular sutures. Drains are unnecessary in most routine cases⁵⁰; in fact, they may introduce harmful effects by promoting ascending infection or fluid management problems if ascites develops postoperatively. We

reserve use of drains for four clinical scenarios: (1) evidence of a clear bile leakage, (2) an infected operative field, (3) operations involving a thoracoabdominal incision (in which a drain is used to ensure that any bile leakage does not develop into a peritoneopleural fistula), and (4) operations involving biliary reconstruction.

LEFT HEPATECTOMY (LEFT HEMIHEPATECTOMY)

Steps 1 through 5

Left hepatectomy involves removal of segments II, III, and IV and sometimes I and IX as well. The first five steps of the procedure are much the same as those of a right hepatectomy, except that the left hemiliver is mobilized by dividing the falciform ligament and left triangular ligaments.

Step 6 (Extrahepatic Dissection and Ligation): Control of Inflow Vessels

Extrahepatic control of vascular inflow vessels can be achieved in essentially the same fashion as in a right-sided resection. Our preference is to start the dissection at the base of the umbilical fissure, dividing the left hepatic artery first. The left portal vein is then easily identified at the base of the umbilical fissure. The point at which the left portal vein is to be divided depends on the extent of the planned parenchymal resection [see Figure 13]; if the caudate lobe is to be preserved, the left portal vein is divided just distal to its caudate branch (line B); if the caudate lobe is to be removed, the left portal vein is divided proximal to the origins of the portal venous branches to the caudate lobe (line A).

Step 6—Alternative (Intrahepatic Pedicle Ligation): Control of Inflow Vessels

If a left hepatectomy is undertaken to treat benign disease or to remove a malignancy that is remote from the base of the umbilical fissure, we recommend performing stapler-assisted intrahepatic pedicle ligation in preference to extrahepatic dissection and ligation.

The left portal pedicle is identified at the base of the umbilical fissure. The hilar plate is lowered through an

incision at hepatotomy site C [see Figure 7], and a second incision is made along the back of segment II at hepatotomy site E [see Figure 7], permitting isolation of the left portal pedicle with minimal risk of injury to the right-sided inflow vessels at the hilum. If the caudate lobe is to be removed as well, incisions should be made at hepatotomy sites C and F [see Figure 7] to allow isolation of the main left portal pedicle proximal to the vessels nourishing the caudate. The portal pedicle is isolated and encircled with an umbilical tape. In the course of dividing the left portal pedicle, the middle hepatic vein, which lies immediately lateral to the left portal pedicle, may be injured. To minimize this risk, firm downward traction is applied to the umbilical tape, and a TA-30 vascular stapler is placed across the left portal pedicle [see Figure 14], which is then stapled and divided.

Step 7: Control of Outflow Vessels

The left hemiliver is reflected to the right, and the entire lesser omentum is divided. The ligamentum venosum is identified between the caudate lobe and the back of segment II and is divided near its attachment to the left hepatic vein; this greatly facilitates identification and dissection of the left and middle hepatic veins anterior to the inferior vena cava. The left and middle hepatic veins are isolated in preparation for division.

Control of the left hepatic vein is quickly and safely accomplished with staple ligation. In approximately 60% of patients, the left and middle hepatic veins join to form a single trunk before entering the vena cava. In a left hepatectomy, the middle hepatic vein may be left intact, in which case, it must be protected while ligating the left. After the left hepatic vein is identified, an endoscopic gastrointestinal anastomosis (GIA)-30 vascular stapler is directed from above downward [see Figure 15] to divide this vessel. The liver is retracted to the right to permit visualization of the junction of the left and middle hepatic veins. If ligation of the middle hepatic vein is desired as well, as is the case when there is tumor in proximity to the vessel, this can be accomplished with a stapler directed along the same path used for left hepatic vein ligation.

Figure 13 Left hepatectomy. Ligation of vascular pedicles at specific sites in the left hemiliver interrupts inflow to specific areas. Ligation at A interrupts inflow to the entire left hemiliver, as well as the caudate lobe. Ligation at B interrupts blood flow to the left liver while sparing the caudate lobe. Ligation at C devascularizes segment II, and ligation at D devascularizes segment III. Ligation at E and F devascularizes segment IV.

Figure 14 Left hepatectomy. After hepatotomies in segment IV and in the back of segment II, the left portal pedicle is isolated, stapled, and divided.

Steps 8 and 9

Parenchymal transection and closure are accomplished in much the same manner in a left hepatectomy as in a right hepatectomy (see above).

OTHER ANATOMIC RESECTIONS

In the following reviews of the other types of major anatomic resections, we focus primarily on the ways in which they differ from right and left hepatectomy. More detailed discussions of these operations are available in specialty texts on liver resection.^{35,36}

Right Trisectionectomy (Extended Right Hepatectomy)

Right trisectionectomy (extended right hepatectomy) involves removal of the right hemiliver along with segment IV, thereby resecting all liver tissue to the right of the falciform ligament [see Figure 3c]. The initial steps of this operation are the same as those for right hepatectomy, up through division of the right inflow vessels and the right hepatic vein.

The next step is devascularization of segment IV. The umbilical fissure is dissected to permit identification of the vascular pedicles to segments II, III, and IV, which lie within this fissure [see Figure 13]. In most patients, the lower part of the umbilical fissure is concealed by a bridge of liver tissue fusing segments II and III to segment IV. After this tissue bridge is divided with diathermy, the ligamentum teres is retracted caudally to reveal the vascular pedicles from the umbilical fissure to segment IV (lines E and F [see Figure 13]). We generally suture-ligate these pedicles before dividing them.

Figure 15 Left hepatectomy. Staple ligation of the left hepatic vein. After the left hemiliver is completely mobilized through division of the left triangular ligament and the lesser omentum, the left hepatic vein is isolated and ligated with an endoscopic GIA vascular stapler. The best angle for introducing the stapler is from the xiphoid posteriorly and caudad.

The liver tissue is then transected immediately to the right of the falciform ligament, from the anterior surface back toward the divided right hepatic vein. The middle hepatic vein is generally left intact until it is encountered in the upper part of the parenchymal transection, at which point it is either suture- or staple-ligated.

Left Lateral Sectionectomy

A left lateral sectionectomy involves removal of only segments II and III, thereby resecting all liver tissue to the left of the falciform ligament [see Figure 3d]. These segments are mobilized by dividing the falciform ligament and left triangular ligaments. As this is done, care is taken to avoid injury to the left hepatic and phrenic veins, which run along the medial portion of the left triangular ligament.

The falciform ligament is retracted caudally, and the bridge of liver tissue between segment IV and segments II and III is divided with diathermy. Dissection is performed along the left of the umbilical fissure. The vascular pedicles to segments II and III are readily dissected and controlled (lines C and D [see Figure 13]). Control of these pedicles within the umbilical fissure is particularly important for tumor clearance if tumor is in proximity to the umbilical fissure: if the condition is benign or if tumor is remote from the umbilical fissure, the liver may be split anteroposteriorly just to the left of the ligamentum teres and the falciform ligament, and the vascular

pedicles may be identified and ligated as they are encountered during the course of parenchymal transection.

Once the inflow vessels have been ligated, the left hepatic vein is identified and divided either before parenchymal transection or as the vessel is encountered near the completion of parenchymal transection. If there is tumor near the dome, it is particularly important for tumor clearance that the left hepatic vein be controlled and ligated early and outside the liver.

Left Trisectionectomy (Extended Left Hepatectomy)

A left trisectionectomy (extended left hepatectomy) involves resection of segments II, III, IV, V, and VIII and sometimes segments I and IX [see Figure 3e]. This is effectively a left hepatectomy combined with a right anterior sectionectomy, with or without resection of the caudate lobe. This complex resection is usually undertaken to excise large tumors occupying the left hemiliver and crossing the principal scissura into the right anterior section.

Throughout this procedure, it is imperative that the right hepatic vein be preserved as it represents the sole venous drainage of the intended hepatic remnant. However, parenchymal transection must often be performed along the course of this vein; therefore, the major risk in the operation is injury to the right hepatic vein, which could result in hemorrhage or hepatic failure from venous congestion of the hepatic remnant. In addition, because the blood supply to segment VII often arises from the right anterior portal pedicle or from the junction of the right anterior and posterior pedicles [see Figure 8], there is a risk of devascularization of a large portion of the hepatic remnant. Finally, the enormous variability of biliary anatomy and the extensive intrahepatic dissection required in this procedure increase the risk of biliary complications.⁵¹ For these reasons, left trisectionectomies are rarely performed outside major centers.⁵²

When planning a left trisectionectomy, particularly close attention must be paid to preoperative imaging investigations so that the right-sided intrahepatic vessels and biliary structures may be accurately delineated. Thin-slice CT and MRI in the form of arterial, portal venous, and hepatic venous reconstructions [see Figure 2] are quite helpful in this regard. For large tumors encroaching on the hepatic hilum or on the junction of the right anterior and posterior pedicles, direct angiography may be helpful on occasion.

The liver is fully mobilized by dividing the peritoneal attachments of the left and right hemilivers. This is essential for identifying the correct plane of parenchymal dissection and for ensuring safe dissection along the right hepatic vein.

The initial dissection is the same as for a left hepatectomy. The liver is turned to the right, the inflow vessels to the left hemiliver are divided, and the left hepatic vein and the subdiaphragmatic inferior vena cava are dissected free. The left and middle hepatic veins are controlled and divided extrahepatically.⁵² The left hemiliver is thus freed, facilitating dissection of the right hemiliver.

Next, the plane of transection within the right hemiliver is defined. This plane runs horizontally and lies lateral to the gallbladder fossa and just anterior to the main right hepatic venous trunk in the right scissura, halfway between the right anterior pedicle and the right posterior pedicle. The plane can be approximated by drawing a line from just anterior to

the right hepatic vein at its insertion into the vena cava to a point immediately behind the fissure of Gans. This line can also be accurately defined by clamping the portal pedicle to the right anterior section of the liver.⁵² If the tumor is remote from the junction of the right anterior and posterior portal pedicles, the anterior pedicle is controlled as outlined earlier [see Right Hepatectomy, Step 6—Alternative (Intrahepatic Pedicle Ligation): Control of Inflow Vessels, *above*]. A vascular clamp is placed on the pedicle and the line of demarcation on the liver surface is carefully inspected before the pedicle is divided. If segment VII appears to be ischemic as well, further dissection must be done to identify and protect the origins of the vessels supplying segment VII.

Parenchymal dissection is carried out from below upward, with bleeding controlled by means of low central venous pressure anesthesia and intermittent application of the Pringle maneuver. If the caudate lobe is to be removed as part of the total resection, the veins draining the caudate must be controlled before parenchymal transection.

Segment-Oriented Resection

Each segment of the liver can be resected independently. In addition, right posterior sectionectomy (removal of segments VI and VII) [see Figure 3f] and right anterior sectionectomy (removal of segments V and VIII) are not uncommon. Extensive descriptions of so-called segment-oriented hepatic resection are available elsewhere.^{53,54}

Postoperative Care

Intravenous fluids administered postoperatively should include phosphorus for support of liver regeneration. For large-volume hepatic resections, electrolyte levels, blood count, and prothrombin time (PT) are checked after the operation and then daily for 3 to 4 days. Packed red blood cells may be administered if the hemoglobin level falls to 8 mg/dL or lower, and fresh frozen plasma may be given if the PT is longer than 17 seconds. Postoperative pain control is best achieved with patient-controlled analgesia or epidural analgesia. Because of the decreased clearance of hepatically metabolized drugs after a major liver resection, selection and dosing of pain medications should be adjusted accordingly. An oral diet can be resumed as early as postoperative day 1 or 2 unless a biliary-enteric anastomosis was performed.

Peripheral edema is common after major hepatic resections and may be treated with spironolactone. Unexplained fevers or isolated hyperbilirubinemia with otherwise normal liver enzymes raises the suspicion for an intra-abdominal biloma, for which CT imaging should be obtained. If a biloma is identified, percutaneous drain placement usually brings about resolution of these collections after a few days, and reoperation is rarely necessary.

Special Considerations

TOTAL VASCULAR ISOLATION FOR CONTROL OF BLEEDING

For control of bleeding during liver parenchymal transection, a technique known as total vascular isolation can be used as an alternative to the Pringle maneuver. In this technique, the liver is isolated by controlling the inferior vena

cava (both above and below the liver), portal vein, and hepatic artery. This approach is based on techniques developed for liver transplantation and on the observation that the liver is capable of tolerating total normothermic ischemia for as long as 1 hour.⁵⁵ Its primary advantage is that while the liver is isolated, little or no bleeding occurs. It does, however, have disadvantages as well. In some patients, temporary occlusion of the inferior vena cava causes hemodynamic instability resulting from reduced cardiac output coupled with increased systemic vascular resistance.⁵⁶ Cardiac failure with marked hypotension, arrhythmia, and even cardiac arrest may ensue. In addition, when hepatic perfusion is restored, the sudden return of stagnant potassium-rich blood to the systemic circulation can aggravate hemodynamic instability. For these reasons, and because bleeding is generally well controlled with low central venous pressure anesthesia, total vascular isolation is useful only in very rare cases. Indeed, one prospective analysis found that total vascular isolation had no major advantages over the approaches described earlier [see Operative Technique, Right Hepatectomy, Step 8: Parenchymal Transection, *above*] and was actually associated with greater blood loss.⁴⁸

The one setting in which total vascular isolation may have a significant role is in the resection of very large tumors that compromise the vena cava or the hepatic veins. To extend the duration of vascular isolation in this setting, venovenous bypass that vents the splanchnic blood into the systemic circulation may be used.⁵⁷ To further minimize parenchymal injury during vascular isolation, the liver may be perfused with cold organ preservation solutions. For extensive vascular invasion that necessitates major vena cava or hepatic venous reconstruction, some authors have suggested that the liver can be removed during venovenous bypass, with resection and reconstruction performed extracorporeally.⁵⁸

Although there are clinical situations that may call for these measures, they are very rarely necessary. Resection and reconstruction of short lengths of inferior vena cava can be performed quite safely without resorting to them. In fact, involvement of the retrohepatic vena cava at a level below the major hepatic veins can generally be treated with simple excision of the affected segment without replacement,⁵⁹ particularly if complete obstruction at this level has already led to established collateral venous circulation.

HANGING MANEUVER IN MAJOR HEPATECTOMY

The classic technique for a right hepatectomy (see above) involves complete mobilization of the right hemiliver before vascular control and parenchymal transection. However, in cases where the tumor has invaded the retroperitoneum or diaphragm, such mobilization may prove exceedingly difficult. Moreover, in cases where the tumor is large, soft, and vascular (e.g., HCC), early mobilization of the right hemiliver may increase the risk of tumor rupture. Finally, division of the vascular inflow and outflow vessels before manipulation of the tumor has the theoretical advantage of preventing vascular dissemination of cancer cells caused by compression of the tumor. For these reasons, some authors have proposed an anterior approach wherein the liver parenchyma is transected first, with ligation of the inflow and outflow vessels performed before mobilization of the right hemiliver.⁶⁰ This approach is now widely followed for resection of HCC.

Subsequently, other authors proposed a modification of this technique, whereby blunt dissection performed along the anterior surface of the vena cava permits passage of a tape that may be used to lift the liver and facilitate parenchymal transection [see Figure 16].⁶¹ The first step in this so-called “hanging maneuver” is to dissect the space between the right and middle hepatic veins in a downward direction for approximately 2 cm. Next, dissection is performed between the vena cava and the caudate lobe on the left side of the inferior right hepatic vein. A clamp is then passed along this plane in the notch between the right and middle hepatic veins, and an umbilical tape is passed for suspension of the liver. Transection of the parenchyma is performed in an anterior-to-posterior direction until the vena cava is reached. The right side of the vena cava is then dissected, and the right hepatic vein and the inferior hepatic veins are ligated. The triangular ligament and the retroperitoneal attachments are transected, and the specimen is removed.

THE CIRRHOTIC PATIENT

The reduction in hepatic functional capacity and reserve present in patients with cirrhosis places them at higher risk for posthepatectomy complications. As a result, the cirrhotic patient requires a very careful assessment of liver function, appropriate selection for surgery, possible alteration of operative technique, and closer attention to perioperative care.

Operative Planning

Selection of patients Hepatic failure is the major cause of hospital death and long-term morbidity after hepatic resection in cirrhotic patients.^{62–66} Consequently, determination of

SCORE

Figure 16 Illustrated is clamp dissection in preparation for the hanging maneuver. (a) A long vascular clamp is passed between the vena cava and the caudate lobe. This clamp is directed at the notch between the right and middle hepatic veins, which has been dissected from above. (b) An umbilical tape is then passed to suspend the plane of parenchymal transection.

a cirrhotic patient's candidacy for hepatectomy is based on a preoperative assessment of baseline liver function.

A variety of tests have been proposed for assessment of hepatic reserve, including measurement of clearance of various dyes and metabolic substrates.^{62,65,67–69} Measurement of elevated hepatic portal venous pressure gradients via invasive radiologic techniques and noninvasive Doppler ultrasonography have also been found to predict postoperative hepatic failure.^{70,71}

Currently, none of these functional tests are routinely performed at most major liver resection centers. In practice, the Child-Pugh score remains the most commonly employed clinical tool for selection of surgical candidates, with Child-Pugh scores higher than 8 being generally accepted as contraindications to major hepatic resection.^{64,66,72–75}

Operative approach The appropriate extent of resection for cirrhotic patients may be quite different from that which may be reasonable for patients without cirrhosis. A guiding principle for hepatectomy in cirrhotic patients is to favor limited resections that spare as much functional parenchyma as possible. In general, even for patients with well-compensated Child class A cirrhosis, we work to limit resections to less than two segments of functional liver. Major hepatic resections involving removal of at least one hemiliver are now reported to carry an operative mortality of less than 10% in cirrhotic patients.^{76,77} However, these procedures are usually performed in cirrhotic patients who have large tumors replacing most of one hemiliver, acceptable liver function, and no atrophy of the uninvolved hemiliver. Patients with large and peripheral tumors are more likely to tolerate a major resection because relatively little functional parenchyma is lost after tumor removal. Resection of small and deep-seated tumors can be more challenging; in such patients where resection might require removal of a large amount of functional hepatic parenchyma, an ablative alternative or even transplantation might be more suitable.

The effort to preserve as much functional liver as possible may make the resection more technically challenging. For example, multiple limited resections may be performed to avoid performing a formal hemihepatectomy.^{78,79} Some go so far as to reconstruct the right hepatic vein for the purpose of preserving venous outflow in segments V and VI after resection of segments VII and VIII. In cirrhotic patients, hepatectomy is most commonly performed for HCC.⁵ For such patients, as long as the resection margin is microscopically clear of cancer, the exact size of the margin does not correlate with the incidence of recurrent disease.⁸⁰ The acceptance of limited margins, coupled with the acceptance of non-anatomic resections aimed at preserving as much functional parenchyma as possible, has been responsible for significant improvements in the safety of hepatic resection in cirrhotic patients worldwide.

Operative Technique

A number of specific technical challenges are posed by the cirrhotic liver that substantially increase the complexity of hepatic resection. The parenchyma of the cirrhotic liver is very firm, making retraction and transection of the liver difficult. In addition, anatomic landmarks are distorted and difficult to locate as a consequence of hepatic fibrosis and

atrophy-hypertrophy. Finally, portal hypertension and tissue friability contribute to increased blood loss during liver mobilization and parenchymal transection.

Exposure and mobilization Trifurcated incisions and thoracoabdominal incisions should be avoided in cirrhotic patients because of the potential for ascites leak externally or into the chest. The increased firmness of the cirrhotic liver and the consequent difficulty of retraction can lead to significant blood loss from retroperitoneal or phrenic collateral vessels during mobilization. To prevent such bleeding, it may be preferable to use an anterior approach in which the liver parenchyma is split within the principal scissura down to the anterior surface of the vena cava before the right hemiliver is mobilized off the retroperitoneum.⁶⁰ The right hemiliver is then mobilized in a medial-to-lateral direction, and the right hepatic vein is secured during mobilization of the right hemiliver off the vena cava.

Inflow control In the past, the safety of the Pringle maneuver in cirrhotic patients has been questioned. More recently, numerous studies have confirmed that hepatic inflow occlusion may be performed for extended periods in cirrhotic patients without increasing operative morbidity or mortality.^{81–86} Nevertheless, it is advisable to employ the Pringle maneuver sparingly in this population so as to minimize ischemic stress. Our practice is to clamp the portal triad with a vessel loop tourniquet for 10-minute periods with 5-minute breaks between. We have not found additional protective maneuvers (e.g., topical cooling^{87,88}) to be necessary.

Parenchymal transection In patients with normal liver parenchyma, most experienced hepatic surgeons use blunt dissection, with either the clamp-crushing technique or the finger-fracture technique, to transect the liver tissue.⁸⁹ In patients with cirrhosis, however, the firmness of the parenchyma makes the clamp-crushing technique less than ideal; because the parenchyma is often harder than the underlying vasculature and biliary radicles, blunt dissection is likely to tear these vessels. As a result, ultrasonic dissectors that coagulate and seal vessels during dissection are more suitable for parenchymal transection in this population.

Closure and drainage Because of the likelihood of postoperative ascites, the abdominal wall is reapproximated with a heavy continuous absorbable monofilament suture to create a watertight closure. To prevent major fluid and protein losses and ascending infections, abdominal drains are generally avoided.⁵⁰ Studies specifically examining the role of drainage in cirrhotic patients have documented a much lower incidence of postoperative complications and a shorter hospital stay for patients in whom no drains were placed.^{90,91}

Postoperative Care

The focus of postoperative care in cirrhotic patients is on the management of cirrhosis and portal hypertension. In most cirrhotic patients who undergo hepatic resection, transient hepatic insufficiency develops postoperatively, characterized by hyperbilirubinemia, ascites formation, hypoalbuminemia, edema, and worsening of baseline coagulopathy.

In the first 24 hours after the procedure, crystalloid must be administered at a level sufficient to maintain adequate portal perfusion.⁹² If patients are stable after the first 24 hours, they are subjected to water and sodium restriction and receive liberal amounts of salt-poor albumin for volume expansion if needed. Spironolactone is started in all patients as soon as an oral diet is resumed, and furosemide is added as needed. On very rare occasions, a peritoneovenous shunt may be employed to control postoperative ascites,⁹³ but this measure is usually unnecessary if patients are properly selected. The PT or international normalized ratio is checked twice daily during the immediate postoperative period; a PT longer than 17 seconds is corrected by administering fresh frozen plasma.

CHEMOTHERAPY-ASSOCIATED STEATOHEPATITIS

One of the most important advances in the treatment of metastatic colon cancer over the past several years has been the development and approval of a number of newer chemotherapeutic agents such as irinotecan, oxaliplatin, cetuximab, and bevacizumab. These agents target the cancer cell cycle, paracrine growth factors, and angiogenic factors and have led to substantial improvements in survival for patients with hepatic colorectal metastases. They are currently being used not only as effective palliative treatment in cases where resection is not feasible but also to downstage unresectable hepatic tumors to permit effective surgical treatment. Consequently, it is now common for patients to be subjected to intensive chemotherapy prior to partial hepatectomy.⁹⁴ Unfortunately, the recognition of hepatotoxic side effects associated with these newer chemotherapeutics has introduced newer challenges in the operative and postoperative management of these patients.⁹⁵

Determination of operative candidacy must therefore include consideration of a condition known as chemotherapy-associated steatohepatitis (CASH).⁹⁶ This disease is associated with a characteristic clinical triad consisting of (1) hepatic steatosis, (2) splenomegaly, and (3) thrombocytopenia. Fatty infiltration of the liver is likely if hepatic attenuation is lower than splenic attenuation on CT imaging, but the absence of this finding does not exclude the possibility of clinically significant steatosis.⁹⁷ Splenomegaly is a sign of portal hypertension, as is refractory consumptive thrombocytopenia. Because this thrombocytopenia is not related to bone marrow suppression, it is not corrected even after chemotherapy is stopped.

When CASH is documented, patients should be selected for partial hepatectomy according to the same criteria used for patients with early cirrhosis. Consideration should also be given to preoperative portal vein embolization (PVE) (see below) before partial hepatectomy to increase the size of the anticipated hepatic remnant.

PREOPERATIVE PORTAL VEIN EMBOLIZATION

Most liver surgeons would be reluctant to resect more than the equivalent of two segments of functional liver in a patient with documented cirrhosis.⁹⁸ Consequently, many cirrhotic patients with technically resectable tumors are relegated to noncurative ablative therapy out of concern for possible postoperative hepatic failure. These limitations may be relieved with the growing use of preoperative PVE, which may extend

the opportunities to undertake major hepatic resections in patients with cirrhosis.

In PVE, access to the portal vein on the side of the liver to be resected is gained via a percutaneous transhepatic approach. The vein is embolized approximately 1 month before the planned resection so as to produce ipsilateral atrophy along with compensatory hypertrophy of the contralateral future hepatic remnant.⁹⁹ The degree of compensatory hypertrophy can be dramatic [see Figure 17] and may modulate postoperative hepatic dysfunction. PVE is also employed in patients with normal parenchyma in whom extensive resection may result in a very small hepatic remnant. In patients undergoing right trisectionectomy, particularly those with a congenitally small left lateral section, the entire area of the extended right hepatectomy, including the main right portal vein and the segmental branches supplying segment IV, can be embolized.¹⁰⁰

There is substantial evidence that preoperative PVE may be successfully used for patients with cirrhosis or impaired hepatic function; moreover, PVE appears to be generally well tolerated for these patients.^{101–103} One immediate benefit of PVE is that it may act as a kind of stress test for the liver, allowing preoperative determination of the likelihood of liver regeneration. If no compensatory hypertrophy is seen 4 weeks after PVE, the decision to perform a major hepatic resection should be reconsidered.

Repeat Hepatic Resection

Since 1984, when one of the earliest descriptions of repeat hepatic resection was published,¹⁰⁴ a number of reports have demonstrated that repeat resection can be performed safely and with good long-term results, even for patients with recurrent malignancy. When appropriately selected, the morbidity and mortality rates associated with repeat partial hepatectomy for metastatic colorectal cancer^{105–117} and HCC^{118–125} are comparable to those observed after initial hepatectomy. Extended survival has been demonstrated, and in selected cases, survival is at least equivalent to that observed after initial resection.^{106,113,120,126} In this section, we concentrate on the key technical aspects of repeat hepatic resection; discussion of indications, patient selection, and outcome are available in other sources.^{106,113,120,126}

Repeat hepatic resection poses unique technical difficulties that are not typically encountered during initial resection.^{105,127,128} First, adhesions at the previous line of parenchymal transection can make reexposure of the liver difficult. Mobilizing the liver off the vena cava and reexposing the porta hepatis and the hepatic veins can be extremely hazardous if dissection was previously undertaken in these areas. Second, liver regeneration and systemic chemotherapy can induce accumulation of fat within the liver, making it more friable¹⁰⁶; this increased parenchymal friability further potentiates the difficulties of exposure and predisposes to inadvertent tearing of the Glisson capsule.¹²⁷ Third, regeneration alters the normal anatomic configuration of the portal structures [see Figure 18].¹²⁹ For example, after right hepatectomy, the porta hepatis is rotated posteriorly and to the right. The normal anatomic relations among the portal structures are altered, with the bile duct becoming displaced posteriorly and the portal vein becoming displaced anteriorly.

Figure 17 Liver atrophy and hypertrophy occur after right portal vein embolization. Shown are images of the liver (a) at baseline and (b) 6 weeks after portal vein embolization. The right hemiliver is outlined in white.

Preoperative imaging is therefore even more important for repeat resections than for primary resections; another reason for this is that postoperative adhesions will limit full access to the liver for intraoperative assessment via palpation or ultrasonography. Before undertaking a repeat resection, it is

essential to know the exact number and locations of the lesions to be treated within the regenerated parenchyma. Preoperative imaging also facilitates operative planning by accurately delineating the vasculature within the regenerated liver.

During repeat resection after a previous major right hepatectomy, preparations should be in place to convert to a thoracoabdominal incision if necessary. Access through the right chest may be required for mobilization of the liver because of dense adherence of the previous resection margin to the diaphragm; alternatively, it may be required for access to the rotated CBD and portal vasculature at the porta hepatis.

During dissection of the right upper quadrant after a previous right hepatectomy, three landmarks are particularly helpful in defining the anatomic structures within the regenerated left hemiliver. The first landmark is the remnant of the ligamentum teres, which defines the demarcation between the left lateral section (segments II and III) and the left medial section (segment IV); these should be identified early during operative exploration. The ligamentum teres may then be followed to the base of the umbilical fissure to define the location of the left hepatic artery. Regardless of whether this artery arises from the common hepatic artery or from the left gastric artery, it passes into the liver parenchyma at the base of the umbilical fissure. The second landmark is the caudate lobe. The lesser omentum should be opened early on to expose this structure, after which an index finger can then be passed in front of the caudate toward the obliterated foramen of Winslow to define the porta hepatis and the location of the portal vein. The third landmark is the vena cava. Performing

Figure 18 Repeat hepatic resection. Depicted are the changes in the relations of the portal structures that occur as a result of right-liver atrophy or resection and left-sided hypertrophy. The structures in the porta hepatis rotate to the right, with the common bile duct coming to rest laterally rather than anteriorly. The Roman numerals refer to the hepatic segments.

a Kocher maneuver to mobilize the duodenum off the vena cava allows this vessel to be dissected, helping to define the portocaval plane. This will define the proper plane for dissection and mobilization of the liver off the vena cava and allows isolation of the hepatoduodenal ligament for application of the Pringle maneuver and for extrahepatic dissection of the inflow vessels.

In a repeat resection after a previous left hepatectomy, the main concern with regard to mobilization of the liver is the anterior displacement of the portal vasculature after right-sided hypertrophy. It is therefore prudent to mobilize the right hemiliver, perform a Kocher maneuver, and follow the vena cava caudally to identify the portal vein from the right. The stomach and the colon are usually adherent against the edge of the previous resection and must be carefully dissected free to allow access to the liver. If the middle hepatic vein was preserved in the earlier left hepatectomy, it will lie immediately deep to the plane of the stomach or the colon and may therefore become a source of hemorrhage during dissection.

Control of the inflow or outflow vasculature may be compromised by scarring resulting from the previous operation. If extensive extrahepatic dissection was performed for control of inflow vasculature in the earlier procedure, control of these vessels in the repeat resection is more safely accomplished via intrahepatic pedicle ligation [see Operative Technique, Right Hepatectomy, Step 6—Alternative (Intrahepatic Pedicle Ligation): Control of Inflow Vessels, *above*].

Another major concern with repeat partial hepatectomy is that it is often necessary to perform more limited resections than would be indicated during a primary resection. During primary resections, we typically avoid wedge excisions as these nonanatomic resections are associated with greater blood loss and a higher likelihood of positive margins compared with anatomic resections.^{112,130} However, during a repeat partial hepatectomy, the absence of multiple inflow or outflow vessels and other anatomic considerations arising in the regenerated liver may make a wedge resection or ablation the best choice.

With appropriate patient selection and careful operative planning, very favorable perioperative and long-term results can be achieved after repeat hepatic resection. Notably, studies of repeat resection have not documented substantial increases in blood loss, operative duration, or complication rates in comparison with initial resection.^{106–110,131}

Laparoscopic Hepatic Resection

In addition to revolutionizing the treatment of gallstone disease,¹³² laparoscopic techniques have been used increasingly for fenestration of benign cysts of the liver^{133,134} and for staging of hepatobiliary malignancies to prevent unnecessary laparotomies.^{38,135–137} Until relatively recently, laparoscopic resection of liver tumors was described only in case reports or small series.^{133,138–142} One reason for the strong resistance to laparoscopic hepatic resection has been fear of catastrophic bleeding. If inadvertent damage to a major hepatic vein or the vena cava occurs during an open operation, the bleeding can be temporarily controlled with direct manual compression until the vessel is repaired; however, if such damage occurs during a laparoscopic operation, initial control of the

bleeding is considerably more difficult. In addition, damage to a hepatic vein or the vena cava during a laparoscopic procedure may theoretically result in CO₂ embolism. Another concern is that the loss of tactile sensation characteristic of laparoscopic surgery may lead to inadequate tumor clearance. Finally, although there are many liver retractors designed to hold the liver in one position, there is no good retractor for repeatedly moving the liver from side to side, as would be necessary during a laparoscopic hepatectomy. The human hand is still the best tool for this purpose.

Laparoscopic hepatic resection has been greatly facilitated by several recent technologic advances, including the introduction of laparoscopic staplers¹⁴³ and ultrasonic dissectors,¹⁴⁴ which can be used for ligation of the hepatic vasculature and transection of liver parenchyma. Another important instrument is the hand access port, a small port through which one hand can be introduced into the abdomen for a hand-assisted laparoscopic resection [see Figure 19].^{145–147} This approach retains a measure of tactile sensation, permits the employment of the hand for optimal liver retraction, and allows for direct manual compression of any bleeding vessels. Furthermore, the incision made for the hand access port can be used for extraction of the resected specimen.

Appropriate patient selection is essential for safe laparoscopic resection of liver tumors. Resection of any two segments along the lower edge of the liver is easily accomplished laparoscopically. We have laparoscopically resected lesions from all segments.⁴⁷ In the following section, we provide a general overview of laparoscopic hepatic resection; more in-depth discussions of the technical aspects of these procedures and the results reported from various centers are available elsewhere.¹⁴⁸

OPERATIVE TECHNIQUE

The patient is placed on the operating table in a supine position and is securely strapped down to allow for rotation of the table. For a right hepatectomy or resection of segments VII and VIII (bisegmentectomy VII, VIII), the patient may

Figure 19 Laparoscopic hepatic resection: hand assisted. Introduction of the hand within the abdomen restores tactile sensation to the surgeon and facilitates resection of the liver. The hand is the best liver retractor available and can be used to dissect the parenchyma. The specimen can be extracted through the hand access port.

be positioned in a left lateral decubitus position, although we have not found this to be universally necessary.

As outlined earlier, a hand access port can be of great utility in laparoscopic liver resection. However, care must be taken in placing the hand port in a location that will not impede access of other trocar sites. For left-sided resection, the hand access port can be placed through a transverse incision in the left upper quadrant [see Figure 19] or through an upper midline incision. For right-sided resection, the port may be placed in the right lower quadrant [see Figure 20b] or through an upper midline incision.

Left-sided resections typically require placement of three to four ports [see Figure 20a]. Pneumoperitoneum is established using an initial port placed at the umbilicus; to prevent gas embolism during liver transection, it is maintained at the lowest pressure possible (typically 10 to 12 mm Hg). A 10 to 12 mm port is placed at the intersection of the subcostal and midclavicular lines to permit dissection of the triangular ligament, hepatic vein, and inferior vena cava. An additional 5 mm port may be placed between the previous two ports to facilitate dissection near the porta hepatic and umbilical fissure. A 10 to 12 mm port is placed in the right midclavicular line to permit the introduction of an endovascular stapler for division of the portal structures and liver parenchyma. We generally use the 45 mm rotating articulated stapler loaded with the white 2.5 mm cartridge.

Right-sided resections generally require placement of four ports. Pneumoperitoneum is again established using a port placed at the umbilicus. If the hand access port is placed in

the right lower quadrant, a 10 to 12 mm port is placed in a subxiphoid position through which an endovascular stapler may be passed for division of the portal structures, liver parenchyma, and hepatic vein. An additional 5 mm port placed in the midepigastrium will facilitate dissection in the porta hepatis, and a 5 mm port placed in a subcostal location along the anterior axillary line will facilitate mobilization of the right hemiliver off the diaphragm and inferior vena cava.

Laparoscopic partial hepatectomy begins with a staging exploration to confirm that the lesion is resectable and, in cases of malignancy, to exclude the presence of distant extrahepatic metastases. IOUS is especially critical in laparoscopic resections for identification of major inflow and outflow vessels, tumor location, and guidance of parenchymal transection. We place a laparotomy sponge into the abdomen to facilitate retraction, absorb blood, and cleanse the laparoscopic camera as needed. A long bulldog clamp may be inserted into the peritoneal cavity in the event that a Pringle maneuver should prove necessary; a long umbilical tape is tied to the bulldog clamp so that the instrument can be easily located throughout the procedure.

Once the liver is mobilized and the tumor is located, the plane of planned transection is marked with the electrocautery. The liver is manually retracted, and parenchymal transection is initiated using ultrasonic dissection. We typically do not attempt to dissect the inflow and outflow vessels extrahepatically. Rather, when parenchymal dissection approaches the major portal pedicles and hepatic veins, we use an endoscopic GIA vascular stapler for transection. After removal of

Figure 20 Shown are the recommended port placements for (a) laparoscopic left lateral sectionectomy and (b) hand-assisted laparoscopic right hepatectomy.

the specimen, the laparoscopic argon beam coagulator and topical agents are used to ensure adequate hemostasis.

As experience with laparoscopic partial hepatectomy is increasing, evidence supporting the safety and oncologic efficacy of major laparoscopic hepatic resections is accumu-

lating.^{149–151} Ongoing analysis of laparoscopic hepatic resection with respect to long-term measures of quality of life and survival continues.

Financial Disclosures: None Reported

24 PROCEDURES FOR BENIGN AND MALIGNANT PANCREATIC DISEASE

*Chad G. Ball, MD, FRCSC, Attila Nakeeb, MD, FACS, and Keith D. Lillemoe, MD, FACS**

Over the past two decades, both the mortality and the morbidity associated with pancreatic surgery have been reduced substantially. In many high-volume centers, the perioperative mortality for pancreatic resection is now less than 3%.¹⁻³ This decline in mortality may be attributed to more careful patient selection, better understanding of surgical anatomy, advances in critical care medicine, and improvements in the management of perioperative complications.

In this chapter, we describe the operative techniques we employ in the management of both benign and malignant pancreatic disease, including pancreaticoduodenectomy (the Whipple procedure), distal pancreatectomy (open and laparoscopic), longitudinal pancreaticojejunostomy (the Puestow procedure), duodenum-preserving pancreatic head resections (Frey and Beger procedures), enteric drainage of pancreatic pseudocysts (open and laparoscopic), and palliative bypass for unresectable periampullary cancer.

Preoperative Evaluation

A number of different imaging options are available to help determine the appropriate surgical approach to management of pancreatic disease. These options include both noninvasive (e.g., transabdominal ultrasonography, computed tomography [CT], and magnetic resonance imaging [MRI]) and invasive modalities (e.g., endoscopic retrograde cholangiopancreatography [ERCP] and endoscopic ultrasonography [EUS]).

Transabdominal ultrasonography can identify changes associated with chronic pancreatitis, biliary and pancreatic duct dilation, and the presence of pseudocysts. In the setting of malignant disease, it may demonstrate dilated intrahepatic and extrahepatic bile ducts, liver metastases, pancreatic masses, ascites, and enlarged peripancreatic lymph nodes. A malignancy of the pancreas typically appears as a hypoechoic mass; ultrasonography reveals a pancreatic mass in 60 to 70% of pancreatic cancer patients.

Helical (spiral) CT is now the preferred noninvasive imaging test for pancreatic disease, having largely supplanted ultrasonography in this context. Helical CT can delineate the anatomy of the pancreas and the surrounding organs in considerable detail. It can also easily define pancreatic calcifications, inflammation, necrosis, and masses. Pancreatic cancer usually appears as an area of pancreatic enlargement with a localized hypodense lesion. A triple-phase intravenous

(IV) contrast study is ideal for the assessment. Thin cuts are obtained through the pancreas and the liver during both the arterial phase and the venous phase after the injection of IV contrast material. Besides determining the primary tumor size, CT can also identify and evaluate invasion into local structures or metastatic disease.

In general, MRI has no significant advantages over CT: its signal-to-noise ratio is low, it is prone to motion artifacts, it does not opacify the bowel, and it has low spatial resolution. Nevertheless, magnetic resonance cholangiopancreatography (MRCP) can be quite useful for defining the anatomy and pathology of the bile ducts and the pancreatic duct noninvasively. It can be especially helpful in cases where the ampulla of Vater is not accessible (as in patients who have previously undergone Roux-en-Y or Billroth II reconstructions).

ERCP allows direct imaging of the pancreatic and bile ducts and is the gold standard for diagnosing chronic pancreatitis. It also allows therapeutic stenting of biliary and pancreatic duct strictures. The sensitivity of ERCP for the diagnosis of pancreatic cancer approaches 90%. The presence of a long, irregular stricture in an otherwise normal pancreatic duct is highly suggestive of a pancreatic malignancy. Often the pancreatic duct is obstructed, with no distal filling.

EUS, although newer than the aforementioned modalities, now plays an important role in the evaluation of pancreatic diseases. It is a semi-invasive test that can be performed with a very low rate of complications (< 0.1%). EUS can diagnose the most common causes of extrahepatic biliary obstruction (e.g., choledocholithiasis and pancreaticobiliary malignancies) with a degree of accuracy equaling or exceeding that of direct cholangiography or ERCP. It is the most sensitive modality for the diagnosis of pancreatic carcinoma. The particular strengths of EUS in the diagnosis of pancreatic cancer include its ability to (1) clarify small (< 2 cm) lesions when CT findings are questionable or negative, (2) detect malignant lymphadenopathy, and (3) guide fine-needle aspiration (FNA) for definitive diagnosis and staging. On average, EUS without FNA is 85% accurate for T stage disease and 70% accurate for N stage disease. The combination of EUS and FNA is 93% sensitive and 100% specific for T stage disease and 88% accurate for N stage disease.⁴

Pylorus-Preserving Pancreaticoduodenectomy (Whipple Procedure)

Surgical resection of a periampullary carcinoma can be accomplished by means of either a pylorus-preserving pancreaticoduodenectomy (PPPD) or the classic Whipple resection (including an antrectomy). Multiple randomized trials have failed to show any significant differences between the two

* The authors and editors gratefully acknowledge the contributions of the previous author, John L. Cameron, MD, FACS, to the development and writing of this chapter.

procedures in terms of either relative ease of performance or short- or long-term outcome (including survival). The choice between them is usually made on the basis of individual surgeons' preferences (unless there is obvious tumor encroachment on the first portion of the duodenum). In the ensuing technical description, we focus primarily on the pylorus-preserving modification but also refer to certain important components of the classic Whipple resection.

OPERATIVE PLANNING

Operative management of periampullary cancer is carried out in three phases. First, the resectability of the tumor is assessed; then, if the tumor is resectable, a pancreaticoduodenectomy is performed, and, finally, gastrointestinal continuity is restored. Selective use of staging laparoscopy should be considered for patients at high risk for occult metastatic disease, such as patients with large primary tumors; patients with lesions in the neck, body, or tail of the pancreas; patients with equivocal radiographic findings suggestive of occult distant metastatic disease (e.g., low-volume ascites, CT findings indicating possible carcinomatosis, and small hypodense regions in the hepatic parenchyma indicating possible hepatic metastases that are not amenable to percutaneous biopsy); and patients with clinical and laboratory findings suggesting more advanced disease (e.g., marked hypoalbuminemia or weight loss, significant increases in the CA19-9 level, and severe back or abdominal pain).

OPERATIVE TECHNIQUE

The peritoneal cavity is entered through an upper midline or a bilateral subcostal incision. The liver, the omentum, and the peritoneal surfaces are inspected and palpated, and suspicious lesions are biopsied and submitted for frozen-section analysis. Regional lymph nodes are examined for evidence of tumor involvement. The presence of tumor in the periaortic lymph nodes of the celiac axis indicates that the tumor has extended beyond the limits of normal resection; however, the presence of tumor in lymph nodes that normally would be incorporated within the resection specimen does not constitute a contraindication to resection.

Once distant metastases have been excluded, the resectability of the primary tumor is assessed. Various local factors may preclude pancreaticoduodenal resection, including retroperitoneal extension of the tumor to involve the inferior vena cava or the aorta and direct involvement or encasement of the superior mesenteric artery (SMA), the superior mesenteric vein (SMV), or the portal vein. Often the determination of resectability is made on the basis of a careful review of the preoperative imaging (CT plus EUS) in conjunction with operative exploration.

Operative assessment of resectability begins with a Kocher maneuver and mobilization of the duodenum and the head of the pancreas from the underlying inferior vena cava and aorta. When the duodenum and head of the pancreas have been mobilized sufficiently, a hand is placed under the duodenum and the head of the pancreas to palpate the tumor mass and determine its relation to the SMA. Inability to identify a plane of normal tissue between the mass and the arterial pulsation indicates that the tumor directly involves the SMA. In these cases, complete tumor resection is not possible.

The final operative step for determining resectability involves dissection of the SMV and portal vein to rule out tumor invasion. Identification of the portal vein is greatly simplified if the common hepatic duct is divided early in the dissection.⁵ Once the hepatic duct has been divided, the anterior surface of the portal vein is easily and quickly identified [see Figure 1]. The lymph node tissue lateral to the hepatic duct and the portal vein should be dissected off the structures to be included in the surgical specimen. It must be remembered that important variations in the hepatic arterial anatomy, including a replaced right hepatic artery, may be encountered during this dissection. If the appropriate plane is found along the anterior surface of the portal vein, it should be easy to pass the index finger of the left hand on top of the vessel posterior to the first portion of the duodenum and the neck of the pancreas (because there usually are no veins joining the anterior surface of the portal vein). If this maneuver proves difficult, the gastroduodenal artery should be identified where it comes off the common hepatic artery. Once adequate dissection has been carried out, the artery should first be clamped with a nonoccluding vascular clamp and then, if the hepatic artery pulse is preserved, divided and ligated with 2-0 silk ties. (The initial clamping of the gastroduodenal artery with a vascular clamp confirms that the arterial supply to the liver will not be interrupted should either variations in hepatic arterial anatomy or important collateral circulation be present in the face of celiac artery stenosis.) After the artery has been divided and ligated, an additional ligature of 3-0 polypropylene should be placed on the proximal stump. Division of the gastroduodenal artery unroofs part of the tunnel through which the index finger is slipped, thereby greatly facilitating the separation of the portal vein from the posterior aspect of the first portion of the duodenum and the neck of the pancreas.

Once the anterior surface of the portal vein has been dissected posterior to the neck of the pancreas, the next step is to identify the SMV and dissect its anterior surface. This is most easily accomplished by extending the Kocher maneuver past the second portion of the duodenum to include the third and fourth portions. During this extensive Kocherization, the first structure encountered anterior to the third portion of the duodenum is the SMV [see Figure 2]. The anterior surface of the vein can then be cleaned and dissected under direct vision by retracting the neck of the pancreas anteriorly. This dissection is continued until it connects to the portal vein dissection from above. If this maneuver can be completed without evidence of SMV or portal vein involvement, the tumor can generally be considered resectable. It is still possible, however, for an uncinate tumor to involve the right lateral surface and the undersurface of the SMV, and this possibility should be carefully evaluated.

If the neck of the pancreas can be successfully dissected off the anterior and lateral surfaces of the portal vein and SMV, most experienced pancreatic surgeons will proceed with pancreaticoduodenectomy without obtaining a tissue diagnosis. In defining the diagnosis of malignancy, an intraoperative biopsy is less conclusive than the combination of the clinical presentation, the results of preoperative CT scanning and cholangiography, and the operative finding of a palpable mass in the head of the pancreas.

Figure 1 Whipple procedure. The common hepatic duct is divided at an early stage to facilitate identification of the portal vein. This division also untethers the first portion of the duodenum and allows it to be retracted anteriorly.

In a PPPD,⁶ the duodenum is first mobilized and divided approximately 2 cm distal to the pylorus with a gastrointestinal anastomosis (GIA) stapler. The posterior surface of the proximal first portion of the duodenum is dissected until the lesser sac is entered. At this point, the soft tissue attachments from the inferior border of the duodenum to the inferior border of the pancreas are divided. The right gastroepiploic vessels, which can be sizable, are clamped, divided, and ligated. In a similar fashion, the soft tissue areolar attachments found superiorly are divided with the electrocautery. The right gastric artery, which comes off the common hepatic artery, is also ligated.

In a classic Whipple procedure, an antrectomy is performed. The right gastroepiploic arcade and the right gastric vessels are divided to permit mobilization of the antrum.

The stomach is then divided with a GIA stapler, usually at the level of the incisura. At this point, if the gastroduodenal artery was not divided earlier, it is identified, divided, and ligated as described (see above). During this step, particular care must be taken to ensure that the lumen of the common hepatic artery is not encroached on by one of the proximal ties.

The neck of the pancreas is then divided with the electrocautery [see Figure 3], with care taken not to injure the underlying SMV and portal vein. These veins are mobilized away from the uncinate process of the pancreas; the dissection should continue until the SMV, clearly palpable with the index finger of the left hand, is visualized. If a replaced right hepatic artery is present, its origin from the SMA will be encountered at this point and must be preserved. The

Figure 2 Whipple procedure. Kocherization of the duodenum is continued along the third portion until the superior mesenteric vein is reached. This vein can then be easily cleaned up to its connection with the portal vein.

uncinate process is divided between clamps flush with the SMA [see Figure 4] and then ligated with 2-0 silk ties; alternatively, either a vessel-sealing system (e.g., LigaSure; Valleylab, Boulder, Colorado) or ultrasonic shears may be used. The SMA is completely exposed during this dissection, which proceeds from cephalad to caudad. As a rule, there are two large veins joining the SMV inferiorly that must be dissected free, doubly ligated, and divided.

Once the uncinate process has been completely divided, the specimen is attached only by the third portion of the duodenum. At this point, the upper abdomen is copiously irrigated with an antibiotic solution and packed. The transverse colon, along with the greater omentum, is reflected cephalad. The proximal jejunum and the ligament of Treitz, along with the fourth portion of the duodenum, are dissected free, and the dissection is continued until it meets the right-side upper abdominal dissection. At a convenient point where there is a wide vascular arcade, the proximal jejunum is divided with a GIA stapler approximately 10 to 12 cm distal to the ligament of Treitz. The proximal jejunum is then grasped with a Babcock clamp and retracted cephalad. The mesentery to the proximal jejunum is divided between clamps and ligated with 2-0 silk (or divided with a vessel-sealing energy device).

When division of the mesentery is complete, the specimen is free and can be removed from the operative field. The bile duct, the pancreatic neck, and the uncinate margins should be tagged with sutures for frozen-section analysis. The bed of the tumor should be carefully inspected for hemostasis and its margins may be marked with ligating clips (e.g., LigaClip; Ethicon Endo-Surgery, Inc., Cincinnati, Ohio) to facilitate postoperative radiation therapy.

There are several technical options for restoring GI continuity after a pancreaticoduodenal resection. Our preferred technique is to bring the end of the divided jejunum through the transverse mesocolon to the right of the middle colic vessels in a retrocolic fashion and to perform an end-to-side pancreaticojejunostomy. A row of interrupted 3-0 silk Lembert sutures is placed between the side of the jejunum and the posterior capsule of the end of the pancreas. A small enterotomy, matching the size of the pancreatic duct, is made in the jejunum, and an inner layer of interrupted 5-0 absorbable monofilament sutures is placed to create a duct-to-mucosa anastomosis [see Figure 5]. Meticulous stitch placement is crucial, and many surgeons use some degree of magnification to complete the anastomosis in small ducts. Often a pediatric feeding tube (either externalized or cut short) is placed across the anastomosis to be used as a temporary indwelling stent.

Figure 3 Whipple procedure. Transection of the neck of the pancreas with electrocautery.

The anastomosis is completed with an outer layer of 3-0 silk Lembert sutures placed between the anterior pancreatic capsule and the jejunum. This layer should be completed in a fashion to invaginate the gland into the seromuscular layer of the bowel. A popular alternative to this duct-to-mucosa technique is to create an enterotomy approximately the same size as the pancreatic neck and to place an inner continuous layer of 3-0 absorbable synthetic suture material circumferentially around the entire gland. The neck is then invaginated 1 to 2 cm into the lumen of the bowel, and an outer interrupted layer of 3-0 silk is placed to complete the anastomosis.

The biliary-enteric anastomosis is performed 6 to 10 cm distal to the pancreaticojejunostomy. An end-to-side hepaticojejunostomy is fashioned with a single interrupted layer of 4-0 absorbable synthetic suture material [see Figure 6]. Generally, there is no need for a T tube or a stent.

Approximately 15 cm distal to the biliary-enteric anastomosis, an end-to-side duodenojejunostomy is performed with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk [see Figure 7]. Some experienced pancreatic surgeons prefer to perform the duodenojejunostomy further distally in an antecolic position, in the belief that doing so reduces the incidence of early postoperative delayed gastric emptying. If an antrectomy was performed, the medial half of the gastric staple line is reinforced with interrupted 3-0 silk seromuscular Lembert sutures. The gastrojejunal anastomosis is completed to the lateral (greater curvature) aspect of the staple line as a two-layer Hofmeister-style anastomosis.

The abdomen is copiously irrigated with an antibiotic solution. The jejunal loop is tacked to the rent in the transverse

mesocolon with interrupted 3-0 silk sutures. The defect in the retroperitoneum previously occupied by the fourth portion of the duodenum is closed with a continuous 2-0 silk suture. One or two closed-suction Silastic drains are placed in the vicinity of the hepaticojejunostomy and the pancreaticojejunostomy and brought out through a stab wound in the right upper quadrant. The abdomen is closed in a standard fashion.

Distal Pancreatectomy with Splenectomy

Distal pancreatic resection is performed for a variety of conditions, including inflammatory processes, benign tumors and cysts, and pancreatic malignancies. The following discussion focuses on distal pancreatectomy for malignancy, but the basic technical principles remain the same for distal pancreatectomy for benign disease.

OPERATIVE TECHNIQUE

The peritoneal cavity is usually entered through a left subcostal incision that extends to the right of midline. In thin patients, an upper midline incision may be employed. On entry into the abdomen, a careful exploration is performed to confirm the absence of disseminated disease.

The lesser sac is entered by dividing the gastrocolic omentum. Generally, this is best done by separating the greater omentum off the transverse colon and leaving it attached to the greater curvature of the stomach. Once the lesser sac has been entered, the posterior wall of the stomach is separated from the pancreas with sharp and blunt dissection to expose the body and tail of the pancreas. The duodenum is Kocherized, and the head and the uncinate process of the pancreas are palpated and visualized; the entire gland can then be inspected and palpated. Intraoperative ultrasonography may be employed for further delineation of the tumor's relation to the surrounding vascular structures.

Once the pancreas has been exposed, the celiac axis and the superior mesenteric vessels are identified and assessed to determine whether the tumor is resectable. The splenic artery is identified where it originates from the celiac axis, and a vessel loop is placed around it. As a result, the vessel is controlled at an early stage of the procedure and can be promptly ligated if bleeding should occur. A patient with a thrombosed splenic vein may have left-side portal hypertension and multiple collateral vessels leading from the spleen to the stomach via the short gastric vessels. With such a patient, it is usually preferable to ligate and divide the splenic artery early in the procedure.

The spleen is retracted toward the midline with the left hand; it should be compressed medially toward the spine rather than retracted anteriorly. It is then mobilized out of the retroperitoneum with the electrocautery. The retroperitoneum usually consists of loose areolar tissue that is easily mobilized. The omental attachments anterior to the hilum of the spleen are divided between Kelly clamps and ligated with 2-0 silk. The line of division is easily determined if the omentum has previously been completely taken off the transverse colon. As the division extends up toward and then along the greater curvature of the stomach, the vasa brevia are encountered and are doubly clamped, divided, and ligated (alternatively, an energy-sealing device may be used). The splenic

Figure 4 Whipple procedure. The uncinate process is divided flush with the superior mesenteric artery.

flexure of the colon is carefully dissected away from the inferior pole of the spleen, and the peritoneal attachments that make up the splenocolic ligament are divided.

The tail and the body of the pancreas are further mobilized out of the retroperitoneum by retracting the spleen and pancreatic tail medially. In the course of this mobilization, care must be taken not to injure the left adrenal gland, which often occupies a fairly superficial position in the retroperitoneum, anterior and medial to the superior pole of the left kidney; care must also be taken not to carry the dissection too deep and thereby risk injuring the kidney or renal vessels. The splenic vein is easily identified in the middle portion of the posterior aspect of the pancreas. The inferior mesenteric vein, which joins the splenic vein at the middle of the body of the pancreas, is identified in the retroperitoneum just lateral to the ligament of Treitz and can be divided at this point.

Further mobilization of the pancreas to the midline exposes the splenic artery where it originates from the celiac axis. As noted (see above), this artery will already have been isolated with a vessel loop. The splenic artery is triply clamped, divided, and triply ligated with 2-0 silk and a 3-0 polypropylene suture near its point of origin.

The SMV can then be identified. A plane is developed by dissecting between the anterior surface of the SMV and the neck of the pancreas; a Penrose drain may be looped around the neck to facilitate exposure. With larger pancreatic cancers, tumor extension into the retroperitoneum may involve the splenic vein. Dividing the pancreatic neck with the electrocautery at this point may facilitate dissection of the splenic vein–portal vein confluence under direct vision. The splenic vein is clamped, divided (without compromising the portal vein–SMV complex), and ligated with 2-0 silk ties

Figure 5 Whipple procedure. (a) An end-to-side mucosa-to-mucosa pancreaticojejunostomy is done in two layers with an outer layer of interrupted 3-0 silk sutures and an inner layer of interrupted 4-0 absorbable synthetic sutures. (b) Alternatively, the end of the pancreas can be invaginated into the end of the jejunum for approximately 2 cm. The anastomosis is done with an outer interrupted layer of 3-0 silk and an inner continuous layer of 3-0 absorbable synthetic suture material.

and a 3-0 polypropylene suture on the proximal stump [see Figure 8]. If there is a pancreatic tumor arising from the proximal body of the gland, the splenic vein may be ligated flush with the SMV. At this location, it is best to oversew the vein with a continuous 4-0 polypropylene suture so as not to compromise the portal vein–SMV complex.

The portal vein and the SMV are carefully dissected away from the undersurface of the neck of the pancreas. Stay sutures of 2-0 silk are placed at the superior and inferior edges of the pancreas proximal to the site of transection, and

Figure 6 Whipple procedure. The common hepatic duct is anastomosed to the jejunum in an end-to-side fashion with a single layer of 4-0 interrupted absorbable synthetic sutures.

Figure 7 Whipple procedure. After the end-to-end pancreaticojejunostomy and the end-to-side hepaticojejunostomy, the duodenum is anastomosed to the jejunum in an end-to-side fashion with an inner continuous layer of 3-0 absorbable suture material and an outer interrupted layer of 3-0 silk.

Figure 8 Distal pancreatectomy. The splenic vein is divided just distal to its junction with the inferior mesenteric vein and then dissected away from the posterior surface of the pancreas from the point of division up to the point where it joins the superior mesenteric vein to form the portal vein.

the neck of the pancreas is divided with the electrocautery (or, alternatively, with a transverse anastomosis or GIA stapler or ultrasonic shears). The operative specimen should be sent for frozen-section evaluation to ensure a negative microscopic margin.

A row of figure-eight sutures of 3-0 absorbable synthetic suture material is placed over the end of the pancreas [see Figure 9]. Using large needles that have been straightened makes this task simple even if the head-neck junction through which the needles are passed is thickened. If the pancreatic duct can be identified, it should be separately oversewn with a figure-eight or mattress suture of 5-0 absorbable synthetic suture material. The resection bed can be marked with titanium clips to guide postoperative radiation therapy if necessary.

The abdomen is copiously irrigated with an antibiotic solution. The pancreatic remnant is drained with a closed-suction Silastic drain brought out through a stab wound in the left upper quadrant. There is no need to drain the splenic bed. The abdomen is then closed in a standard fashion.

Laparoscopic Distal Pancreatectomy with or without Splenectomy

Selected patients may benefit from a laparoscopic spleen-preserving distal pancreatectomy (SPDP) or a laparoscopic distal pancreatectomy with splenectomy. Conditions that are

Figure 9 Distal pancreatectomy. A row of overlapping horizontal mattress sutures is placed in the neck of the pancreas just proximal to where it is to be divided, the neck is divided with the electrocautery, and a row of figure-eight sutures of 3-0 absorbable synthetic suture material is placed over the end of the pancreas.

potentially amenable to treatment with a laparoscopic distal pancreatectomy include benign or premalignant cystic neoplasms, islet cell tumors of the pancreas, chronic pancreatitis with symptomatic ductal obstruction, and pancreatic pseudocysts confined to the distal body and tail of the pancreas.

OPERATIVE TECHNIQUE

The patient can be placed either supine in a low lithotomy position or in a semilateral position with the left side up. For lesions in the distal body or tail of the pancreas, we prefer the semilateral position; for lesions closer to the neck of the pancreas, we prefer the low lithotomy position. Four to five ports are placed [see Figure 10], and a 10 mm 30° laparoscope is used. As in all pancreatic procedures, the peritoneal surfaces, the omentum, the mesentery, and the viscera should each be carefully inspected to rule out metastatic disease. Intraoperative ultrasonography may be employed to evaluate the liver and locate the lesion in the pancreas.

The body and tail of the pancreas are exposed by opening the lesser sac. The gastrocolic omentum is divided and widely mobilized with an ultrasonic scalpel (e.g., Harmonic Scalpel; Ethicon Endo-Surgery, Inc., Cincinnati, Ohio), with care taken to stay outside the gastroepiploic vessels. Either a retractor is advanced into the lesser sac through the sub-xiphoid port or suture retraction to the abdominal wall is employed to elevate the stomach anteromedially. The splenocolic ligament is divided, and the splenic flexure of the colon is reflected inferiorly.

Figure 10 Laparoscopic distal pancreatectomy. Shown is the placement of ports for distal pancreatectomy.

After these maneuvers, the inferior pancreatic margin is exposed. The peritoneum is then incised along the inferior pancreatic border, and the pancreatic body is separated from the retroperitoneum by means of sharp and blunt dissection along its inferior border. Laparoscopic ultrasonography and direct visual inspection, combined with the findings from pre-operative imaging, may be employed to determine the extent of the dissection. Initially, the dissection should be directed so that it is medial to the pancreatic lesion. The pancreatic body is elevated by means of blunt and sharp dissection, after which the splenic vein should be easily identifiable [see Figure 11]. Care must be exercised to prevent inadvertent injury to this vessel. Once the splenic vein has been identified, a careful circumferential dissection around the splenic vein is performed with a right-angle clamp, and a vessel loop is placed around the vein. This dissection helps identify the splenic artery as well, which also is controlled with a vessel loop. These precautionary measures allow quick control of bleeding should a vascular tear occur later in the procedure.

Figure 11 Laparoscopic distal pancreatectomy. Once the pancreatic body has been mobilized from the retroperitoneum, the splenic vein can be identified.

Once the pancreatic body has been adequately mobilized from the splenic vessels, the pancreatic parenchyma is divided. This may be done with an endoscopic stapler, but we prefer using the ultrasonic scalpel. Once the proximal pancreatic tissue is divided, the specimen is grasped and gently retracted anteriorly to allow further dissection of the vessels. The dissection proceeds toward the splenic hilum in a medial-to-lateral direction. The pancreatic branches of the splenic vein are sequentially identified, dissected free with laparoscopic Metzenbaum scissors, and divided with the ultrasonic scalpel [see Figure 12]. The branches of the splenic artery, which runs just superior to the vein, are treated similarly. Special care must be taken as the dissection approaches the hilum of the spleen.

At the completion of an SPDP, the specimen is placed and removed in a standard endoscopic retrieval device (e.g., Endo Catch; United States Surgical, Norwalk, Connecticut). Some surgeons then oversew the pancreatic remnant with a series of interrupted absorbable horizontal mattress sutures. Alternatively, the exposed end of the pancreatic remnant can be sealed with an energy device. A single round Jackson-Pratt drain is placed near the pancreatic transection line and brought out through one of the 5 mm lateral ports.

An alternative approach to SPDP involves dividing the splenic vessels proximally and distally while preserving the short gastric and left gastroepiploic vessels to maintain splenic perfusion [see Figure 13]. The initial steps of this technique are essentially the same as those already described (see above), up to the division of the pancreas. In the alternative approach to SPDP, after pancreatic transection, the splenic artery and vein are divided with an endovascular stapler. The left portion of the pancreas is lifted up and mobilized posteriorly along with the splenic artery and vein, and the vessels are again divided as they emerge from the pancreatic tail to enter

Figure 12 Laparoscopic distal pancreatectomy. After having been transected, the distal portion of the pancreas is dissected away from the splenic vessels in a medial-to-lateral direction. The pancreatic branches of the splenic vessels are divided sequentially as they are encountered.

Figure 13 Laparoscopic distal pancreatectomy. In an alternative approach to spleen-preserving distal pancreatectomy, the splenic artery and the splenic vein are divided, and the viability of the spleen is maintained by preserving the short gastric and left gastroepiploic vessels.

the hilum of the spleen. The spleen is then supplied solely by the short gastric vessels and the left gastroepiploic vessels.

If an en bloc distal pancreatectomy with splenectomy is performed, the splenic artery and vein are divided after the pancreas is transected. The distal pancreas is dissected free in a medial-to-lateral direction. The short gastric vessels are divided with an ultrasonic scalpel, with care taken not to injure the stomach wall. The retroperitoneal attachments of the spleen and the tail of the pancreas are also divided with the ultrasonic scalpel. The specimen is then placed in a specimen retrieval bag and extracted from a port site that has been enlarged to a size of 3 to 6 cm. To facilitate extraction of the specimen, the spleen may be morcellated within the bag.

Laparoscopic Pancreatic Enucleation

Recently, laparoscopic techniques have been applied to the enucleation of benign neuroendocrine tumors of the pancreas. This approach is indicated for tumors located in the body and tail of the pancreas that do not appear to involve the pancreatic duct on preoperative imaging. Patient positioning and trocar placement are similar to those for laparoscopic distal pancreatectomy (see above). The body and tail of the pancreas are widely exposed by entering the lesser sac through the gastocolic omentum. Intraoperative ultrasonography is again useful for the identification of the tumor and to further delineate the relationship of the lesion to the splenic vessels and the pancreatic duct. The lesion can then be dissected out of the pancreatic parenchyma using the ultrasonic shears or electrocautery. The specimen is placed in a retrieval bag and removed. The enucleation bed is then inspected for hemostasis and a closed-suction drain is placed to control any potential pancreatic leak.

Longitudinal Pancreaticojejunostomy (Puestow Procedure)

OPERATIVE TECHNIQUE

The abdomen is entered through an upper midline or bilateral subcostal incision. The lesser sac is accessed by removing the greater omentum from the transverse colon along virtually its entire length, thereby exposing the tail, body, neck, and head of the pancreas. The pancreas often appears markedly fibrotic and scarred. The posterior wall of the stomach may be adherent to a portion of the body of the pancreas as a result of multiple episodes of inflammation; if it is adherent, it is easily dissected free. The duodenum is Kocherized, and the head and the uncinate process of the pancreas are palpated from both an anterior and a posterior direction. In many cases, the pancreatic duct is markedly dilated and can actually be palpated through the anterior surface in the middle portion of the body of the pancreas. The rest of the abdomen is explored to check for the presence of other pathologic conditions. To confirm the position of the dilated pancreatic duct, a 20-gauge needle on a 10 mL syringe is used to aspirate the duct. The use of intraoperative ultrasonography can be quite helpful to identify the dilated pancreatic duct. Once pancreatic juice is obtained, the syringe is removed from the needle hub, with the needle left in place.

The pancreatic duct is entered by dividing the pancreatic parenchyma with the electrocautery on either side of the needle. A large right-angle clamp is inserted, and the duct is filleted open with the electrocautery both proximally and distally [see Figure 14]. Small pancreatic ductal concretions are carefully removed. At least 6 cm of the duct must be opened to yield a good chance of long-term success. Ideally, if the

Figure 14 Puestow procedure. The dilated pancreatic duct is filleted open with the electrocautery both proximally and distally. At least 6 cm of the duct should be opened.

duct is dilated all the way out to the tail, it can be filleted open virtually to the tip of the pancreas. In the proximal direction, the duct can easily be opened as far as the neck of the pancreas. Beyond this point, however, the duct passes posteriorly and inferiorly into the head of the pancreas; because the head can be very thick, opening up the duct any further can be difficult.

A Bakes dilator is carefully passed proximally through the open pancreatic duct, down through the pancreatic duct in the unopened head, through the ampulla of Vater, and into the duodenum. If a Bakes dilator cannot be passed into the duodenum, some surgeons elect to open the duodenum and perform a sphincteroplasty, so that by working both from within the duodenum and from within the open pancreatic duct, they can ensure the patency of the entire pancreatic duct.

A Roux-en-Y jejunal loop approximately 50 cm long is constructed. The most proximal loop of jejunum in which there is a good vascular arcade is selected. A 2 cm segment of this loop is cleaned and divided with a GIA stapler. The small bowel mesentery is divided between clamps down through the arcade vessel and is ligated with 3-0 silk. The end of the distal jejunum is oversewn with a layer of 3-0 silk Lembert sutures. Alimentary tract continuity is reestablished by means of an end-to-side jejunojejunostomy, in which the most proximal portion of the divided jejunum is anastomosed to the side of the Roux-en-Y jejunal loop 50 cm distally with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk. The defect in the small bowel mesentery is closed with a continuous 4-0 silk suture.

The Roux-en-Y jejunal loop is brought up into the lesser sac in a retrocolic position through a small rent in the transverse mesocolon. A side-to-side pancreaticojejunostomy is performed in two layers. Before the Roux loop is opened, an outer interrupted layer of 3-0 silk is placed between the jejunal loop and the pancreatotomy, passing through the capsule of the pancreas and out through the opened pancreatic parenchyma along the inferior border of the pancreas. When this layer is complete, an enterotomy approximately 2 mm from the jejunal suture line is made along the entire length of this line. Starting at the distal pancreatic tail, an inner continuous layer of 3-0 absorbable synthetic suture material is placed in an over-and-over locking fashion through the entire wall of the jejunum and the entire divided surface of the pancreas and into the duct [see Figure 15]. The inner layer of the superior suture line is placed in an over-and-over fashion without locking, again with a continuous 3-0 absorbable synthetic suture. The outer layer of the superior suture line consists of interrupted 3-0 silk sutures placed in a Lembert fashion.

When the pancreatic duct is dilated to a diameter of 1 cm or greater, a two-layer anastomosis is possible and is, in fact, preferred. When the diameter of the duct is between 5 mm and 1 cm, however, a two-layer anastomosis is generally difficult, and a one-layer anastomosis is preferred. A single layer of interrupted 3-0 silk sutures is placed so that the knots are tied on the outside. This is easily accomplished with the superior suture line. With the inferior suture line, which is placed first, the suture passes from outside inward on the pancreas and then from inside outward on the jejunum. In a single-layer side-to-side pancreaticojejunostomy, the jejunostomy must be performed before any sutures are placed.

Figure 15 Puestow procedure. When the diameter of the dilated pancreatic duct is 1 cm or wider, a side-to-side pancreaticojejunostomy should be done in two layers. Once an outer layer of interrupted 3-0 silk sutures is placed between the jejunal loop and the pancreatotomy, an enterotomy is made along the entire length of the jejunal suture line, and an inner layer consisting of a continuous 3-0 absorbable synthetic suture is placed.

The procedure is completed by tacking the Roux-en-Y jejunal loop to the rent in the transverse mesocolon with interrupted 3-0 silk sutures. The pancreaticojejunostomy is drained with closed-suction Silastic drains placed on either side of the anastomosis and brought out through separate stab wounds in the left upper quadrant. The abdomen is copiously irrigated with an antibiotic solution and closed in a standard fashion.

Duodenum-Preserving Pancreatic Head Resection (Frey Procedure)

The Frey procedure is indicated in patients with symptomatic chronic pancreatitis and (1) multiple pancreatic duct strictures, (2) an enlarged fibrotic pancreatic head with multiple impacted ductal calculi, and/or (3) a dilated obstructed main pancreatic duct.

OPERATIVE TECHNIQUE

The peritoneal cavity is entered through either a midline or bilateral subcostal incision, and the abdomen is explored. An extensive Kocher maneuver is completed, followed by division of the gastrocolic ligament to obtain exposure to the anterior surface of the pancreas. The pancreatic duct is identified in the body of the gland via inserting a 20-gauge needle on a 10 mL syringe while aspirating. Once the duct is located, it is opened longitudinally along its length using electrocautery (as in a Puestow procedure). Classically, hemostatic absorbable sutures are also placed between the pancreas and the inner layer of the duodenum. A probe inserted into the pancreatic duct toward the ampulla is helpful for identification of the duct trajectory. The head of the pancreas is then cored out using electrocautery. This leaves a pancreatic cuff along the inner duodenum with an intact posterior pancreatic capsule. It should be noted that the surgeon's left hand is placed behind the pancreas to assist in determining the depth of this coring-out process. Care is also taken not to injure the bile duct at this level. The distal pancreatic duct within the remaining head (1.5 to 2.0 cm) is probed to ensure that all calculi have been removed. Once completed, a standard

Roux-en-Y jejunal limb is brought up through a defect in the transverse mesocolon to create a pancreaticojejunostomy. This anastomosis does not have to precisely approximate the pancreatic duct to the jejunal mucosa. It is generally completed in one or two layers using a 3-0 absorbable monofilament suture. The jejunojejunostomy should be constructed in the standard manner to create a 60 cm Roux-en-Y limb. Closed-suction drainage adjacent to the pancreas is optional. The abdomen is closed in a standard fashion.

Duodenum-Preserving Pancreatic Head Resection (Beger Procedure)

The Beger operation begins with the same steps as the Whipple procedure. The peritoneal cavity is entered through either a midline or bilateral subcostal incision, and the abdomen is explored. An extensive Kocher maneuver is completed prior to dividing the gastocolic ligament to obtain exposure to the anterior surface of the pancreas. The superior mesenteric and portal veins, as well as the common hepatic artery and bile duct, are identified. The portal vein is then dissected off the posterior pancreatic capsule in the same manner as during a Whipple procedure. Caution must be employed during this step, given the frequent inflammatory attachments between the pancreas and the portal vein as a result of chronic pancreatitis. The gastroduodenal artery is doubly ligated once it has been test occluded. The neck of the pancreas is then transected using electrocautery with special attention to identifying the main pancreatic duct during transection. The pancreatic head is then rotated 90° into an anterior-posterior position prior to its complete separation from the portal vein. Mobilizing the portal vein typically entails the ligation of two small branches during this step. The subtotal resection of the pancreatic head is synonymous to that performed during the Frey procedure. Again, a probe inserted into the pancreatic duct toward the ampulla is helpful for identification of the duct trajectory. Reconstruction involves two pancreaticojejunostomies after a Roux-en-Y limb of jejunum is passed to the pancreatic head in a retrocolic manner. The first anastomosis is completed between the remaining left pancreas and the jejunum in a side-to-end manner. This two-layer duct to mucosa anastomosis is the same as during a Whipple procedure. The second anastomosis is a one- or two-layer side-to-end pancreaticojejunostomy approximately 8 cm distal to the left pancreatic anastomosis. The jejunal incision approximates 5 cm in length, and the anastomosis is identical to the one described during the Frey procedure. Finally, a distal jejunojejunostomy is created to complete the 60 cm Roux-en-Y limb. It should also be noted that in patients with multiple stenoses of a dilated main pancreatic duct, the duct can also be opened longitudinally toward the tail of the gland. A side-to-side pancreaticojejunostomy, identical to a Puestow procedure, is then completed.

Drainage of Pancreatic Pseudocyst

OPERATIVE TECHNIQUE

Drainage into Roux-en-Y Jejunal Loop

The peritoneal cavity is entered through a midline incision, and the abdomen is explored. Typically, a substantial mass

that is cystic and easily ballotable is palpable posterior to the stomach. The duodenum and the head of the pancreas are Kocherized so that the head may be palpated both anteriorly and posteriorly. The physical characteristics of chronic pancreatitis are usually present. The body and the tail of the pancreas are palpated as well; the pancreas is usually fibrotic, firm, and somewhat enlarged. The rest of the abdomen is explored to check for the presence of other pathologic conditions.

At this point, the size and configuration of the cyst are compared with the findings on the preoperative CT scan. If the CT scan shows a unilocular solitary cyst and if, at the time of laparotomy, there appears to be a mass that coincides exactly with what is observed on the CT scan, there is no need to enter the lesser sac. The lesion can be drained into a Roux-en-Y jejunal loop through the transverse mesocolon, and the lesser sac need not be explored. Most pseudocysts are formed by anterior disruptions of the main pancreatic duct. When pancreatic secretions leak out into the lesser sac, the body walls off the leak through an inflammatory response. The transverse mesocolon becomes adherent to the posterior wall of the stomach, which in turn adheres to other adjacent structures in and around the retroperitoneum. As a result, the leak is sealed off. Thus, the transverse mesocolon is usually the inferior and most dependent portion of the pseudocyst, and this site is the ideal location for drainage [see Figure 16].

Figure 16 Drainage of pancreatic pseudocyst into Roux-en-Y jejunal loop. The transverse mesocolon is usually the most inferior and dependent part of a pancreatic pseudocyst; thus, drainage through the transverse mesocolon into a Roux loop is usually the ideal approach.

The transverse colon is retracted cephalad, and the cyst is easily visualized and palpated through the transverse mesocolon. The location of the cyst is confirmed by aspirating pancreatic juice through the transverse mesocolon with a 10 mL syringe and a 20-gauge needle. The middle colic vessels must be carefully identified and avoided. A 60 cm long Roux-en-Y jejunal loop is constructed. The proximal jejunum is divided with a GIA stapler at the first convenient arcade. The small bowel mesentery is divided down through the arcade. The distal end of the jejunum is inverted with an interrupted layer of 3-0 silk Lembert sutures.

Alimentary tract continuity is reestablished by means of an end-to-side jejunojejunostomy, in which the proximal jejunum is anastomosed to the side of the Roux-en-Y jejunal loop 60 cm from the inverted end. This anastomosis is performed with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk. The rent in the small bowel mesentery is closed with a continuous 3-0 silk suture.

A side-to-side cystojejunostomy is performed with an outer interrupted layer of 3-0 silk and an inner continuous layer of 3-0 absorbable synthetic suture material. The posterior outer layer of the anastomosis consists of a series of 3-0 silk sutures passed through and through the jejunal loop and through and through the transverse mesocolon (which is the inferior wall of the pseudocyst) [see Figure 17]. The suture line should be

Figure 17 Drainage of pancreatic pseudocyst into Roux-en-Y jejunal loop. The outer posterior layer of the side-to-side cystojejunostomy comprises a series of 3-0 silk sutures placed through and through the jejunal loop and the transverse mesocolon.

approximately 2.5 to 5 cm long. After the posterior layer has been secured, a cystotomy is performed with the electrocautery. An ellipse of cyst wall is removed and sent for frozen-section examination. No matter how clear it seems to be that the lesion is a pseudocyst, a specimen from the cyst wall should always be sent for frozen-section examination. Some of these lesions are cystic neoplasms, which must be resected rather than drained. If no epithelial lining is found on frozen-section examination, it is safe to assume that the lesion is not a cystic neoplasm but a pancreatic pseudocyst and to proceed accordingly.

A parallel enterotomy is made in the jejunum. An inner continuous layer of 3-0 absorbable synthetic suture material is placed inferiorly in a locking fashion and then brought around superiorly in a Connell stitch. An outer interrupted layer of 3-0 silk is placed superiorly. With the cyst decompressed, a sizable lumen should be easily palpable in the anastomosis between the cyst and the jejunal loop.

A closed-suction Silastic drain is left near the anastomosis and brought out through a stab wound in the left upper quadrant. The abdomen is copiously irrigated with an antibiotic solution and closed in a standard fashion.

Drainage into Stomach

The peritoneal cavity is entered through an upper midline incision, and the abdomen is explored. Typically, a pseudocyst that is not amenable to drainage through the transverse mesocolon presents as a mass that is cystic and is palpable through the anterior wall of the stomach and the lesser omentum in the upper abdomen; such a mass is not generally palpable through the root of the transverse mesocolon with the transverse mesocolon reflected cephalad and thus is not easily drained into a Roux-en-Y jejunal loop. The duodenum and the head of the pancreas are Kocherized, and the head of the pancreas is palpated. Signs of chronic pancreatitis are invariably present. The rest of the abdomen is explored to check for the presence of other pathologic conditions.

Stay sutures of 3-0 silk are placed in the anterior wall of the body of the stomach. A transverse gastrotomy is made with the electrocautery. The cyst wall is easily palpable through the posterior wall of the stomach. The location of the cyst is confirmed by aspirating pancreatic juice through the back wall of the stomach with a 10 mL syringe and a 20-gauge needle. The mass palpated at the time of operation is compared with the cyst as it appears on the preoperative CT scan. If the CT scan shows a solitary unilocular cyst that corresponds to the palpable mass identified at the time of laparotomy, it is safe to conclude that the cyst is solitary and can be drained effectively into the stomach.

A transverse incision is made with the electrocautery through the posterior wall of the stomach, through the cyst wall, and into the pseudocyst. It is often desirable to leave the 20-gauge needle in place and to perform the posterior wall gastrotomy on either side of the needle. An ellipse of cyst wall is sent for frozen-section examination. Again, this step is mandatory, no matter how obvious it seems that the lesion is an inflammatory cyst. A continuous locking suture of 3-0 absorbable synthetic material is placed through and through the posterior wall of the stomach and the anterior wall of the cyst [see Figure 18]. This step may or may not actually be important for achieving long-term patency of the opening

Figure 18 Drainage of pancreatic pseudocyst into stomach. Once an incision has been made through the posterior wall of the stomach, through the cyst wall, and into the pseudocyst, a continuous locking 3-0 absorbable synthetic suture is placed through and through the posterior wall of the stomach and the cyst wall.

between the cyst and the posterior wall of the stomach, but it does ensure good hemostasis. The anterior gastrotomy is closed with an inner continuous layer of 3-0 absorbable synthetic suture material in a Connell stitch and an outer interrupted layer of 3-0 silk. The abdomen is closed in a standard fashion. It should also be noted that drainage may be achieved endoscopically in many cases.

Laparoscopic Drainage of Pancreatic Pseudocysts

Five distinct laparoscopic approaches have been described for the treatment of pancreatic pseudocysts: (1) transgastric cystgastrostomy, (2) intragastric cystgastrostomy, (3) mini-laparoscopic intragastric cystgastrostomy, (4) cystgastrostomy via the lesser sac approach, and (5) Roux-en-Y cystjejunostomy.

The laparoscopic transgastric cystgastrostomy involves making an anterior gastrotomy, followed by using electrocautery to open the cyst wall through the posterior wall of the stomach. A cystgastrostomy can then be created using an endoscopic stapler or via a handsewn anastomosis with intracorporeal suturing. Intragastric cystgastrostomy involves inserting trocars percutaneously through the abdominal wall and directly into the gastric lumen using simultaneous laparoscopic and gastroscopic guidance. Cautery and sharp dissection are used to create the cystgastrostomy. The mini-laparoscopic intraluminal cystgastrostomy is performed in a similar fashion, with the exception that 2 mm intragastric ports are used to minimize invasiveness and trauma to the anterior gastric wall. Laparoscopic cystgastrostomy via the lesser sac approach is becoming the preferred approach when the anatomy is favorable. The advantages of this approach include the avoidance of an anterior gastrotomy, as well as the assurance of a large anastomosis that is not dependent on the adherence of the cyst to the posterior gastric wall. Because the entire anastomosis is either stapled or sutured, the risk of bleeding is minimized. The technique involves creating a window in the gastrocolic omentum through which the lesser sac is entered. The stomach is then elevated, and a cystotomy is made adjacent to a posterior gastric wall gastrotomy. A cystgastrostomy is then created with an endoscopic stapler, followed by a suture closure of the opening.

For large cysts, or those not in direct contact with the posterior wall of the stomach, a laparoscopic Roux-en-Y cyst jejunostomy can be performed. The omentum and transverse colon are retracted cephalad and the pseudocyst can often be visualized through the transverse mesocolon. Laparoscopic ultrasonography can also be used to help identify the location of the cyst. The jejunum is divided approximately 30 cm distal to the ligament of Treitz to create a Roux limb. The pseudocyst is next opened with the Harmonic Scalpel through the transverse mesocolon. A small enterotomy is made in the Roux limb, and a stapled cyst jejunostomy can be performed. The cyst enterostomy is then closed with a running suture. The procedure is completed with the jejunojunction performed at least 30 cm distal to the cyst jejunostomy.

Palliative Bypass for Unresectable Periapillary Cancer

The peritoneal cavity is entered through an upper midline incision, and the abdomen is examined for evidence of liver metastases, serosal spread, carcinomatosis, involvement of regional lymph nodes, and invasion of major vascular structures. Once the tumor has been shown to be unresectable and histologic confirmation of malignancy has been received, a palliative double-bypass procedure is begun, in which the duodenum is bypassed with a retrocolic gastrojejunostomy and the distally obstructed biliary tree is bypassed with a

hepaticojejunostomy. A chemical splanchnicectomy is also performed to reduce pain.

Approximately 4 cm of the most dependent portion of the greater curvature of the stomach is cleaned by doubly clamping, dividing, and ligating attachments of the greater omentum. Once this is accomplished, a small rent is made in the transverse mesocolon, and a proximal loop of jejunum is brought up through this rent and anastomosed in an isoperistaltic fashion to the dependent wall of the stomach. The anastomosis is performed with an outer interrupted layer of 3-0 silk and an inner continuous layer of 3-0 absorbable synthetic suture material.

In the past, palliative duodenal bypasses for pancreatic cancer were frequently performed by carrying out an anterior antecolic gastrojejunostomy. Delayed gastric emptying proved to be a common occurrence with this approach. Fortunately, this complication can be virtually eliminated by performing a posterior gastroenterostomy. Once the posterior gastroenterostomy is complete, the anastomosis is tacked to the rent in the transverse mesocolon on the gastric side with interrupted 3-0 silk sutures to prevent the afferent and efferent jejunal limbs from herniating up through the transverse mesocolon [see Figure 19].

Figure 19 Palliative double bypass for unresectable pancreatic cancer. Once the retrocolic gastrojejunostomy is complete, the anastomosis is tacked to the rent in the transverse mesocolon on the gastric side with interrupted 3-0 silk sutures.

The gallbladder is mobilized out of the liver bed in a retrograde fashion and placed on traction to facilitate identification of the common hepatic duct. Once identified, the common hepatic duct is divided just proximal to the cystic duct. The gallbladder is removed, and the distal biliary segment is oversewn with a continuous 3-0 polypropylene suture. The jejunum is divided approximately 30 cm distal to the gastrojejunostomy, and a Roux-en-Y limb is brought up into the right upper quadrant through a second opening in the transverse mesocolon. An end-to-side hepaticojejunostomy is performed with a single layer of interrupted 4-0 absorbable synthetic sutures [see Figure 20]. An end-to-side jejunojejunostomy is then performed 60 cm downstream to restore enteric continuity and complete the Roux-en-Y. This anastomosis is performed with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk. The Roux-en-Y limb is tacked to the opening in the transverse mesocolon to prevent herniation.

The lesser omentum is divided, and a chemical splanchnicectomy is performed by injecting 20 mL of 50% alcohol into the celiac plexus on each side of the aorta at the level of the celiac axis using a 22-gauge needle. The level of the celiac axis is easily determined by palpating the thrill that is invariably present in the common hepatic artery as it comes off the celiac axis.

A closed-suction Silastic drain may be left posterior to the area of the hepaticojejunostomy and brought out through a stab wound in the right upper quadrant. If tissue confirmation of the presence of adenocarcinoma of the head of

Figure 20 Palliative double bypass for unresectable pancreatic cancer. An end-to-side hepaticojejunostomy is performed, followed by a side-to-side jejunojejunostomy between the afferent loop leading to the biliary anastomosis and the efferent loop leading from it. An opening is made in the lesser omentum, and a chemical splanchnicectomy is performed by injecting alcohol into the celiac plexus.

the pancreas was not obtained preoperatively, it should be obtained during the operation. As a rule, this is most easily accomplished by performing a transduodenal needle biopsy (e.g., with a Tru-Cut needle; Cardinal Health, Dublin, Ohio).

The abdomen is irrigated with an antibiotic solution and closed in a standard fashion.

25 SPLENECTOMY

Eric C. Poulin, MD, MSc, FACS, FRCSC, Christopher M. Schlachta, MDCM, FACS, FRSCS, and Joseph Mamazza, MDCM, FRSC

Medicine is not an exact science, and nowhere is this observation more appropriate than in the operating room when a spleen is being removed.¹

The first reported splenectomy in the Western world was performed by Zacarello in 1549, although the veracity of his operative description has been questioned. Between this initial report and the 1800s, very few cases were recorded. The first reported splenectomy in North America was performed by O'Brien in 1816. The patient was in the act of committing a rape when his victim plunged a large knife into his left side. As in this case, most early splenectomies were done in patients who had undergone penetrating trauma; often the spleen was protruding from the wound, and the surgeon proceeded with en masse ligation. The first elective splenectomy was performed by Quittenbaum in 1826 for sequelae of portal hypertension, and soon afterward, Wells performed one of the first splenectomies using general anesthesia; both patients died. In 1866, Bryant was the first to attempt splenectomy in a patient with leukemia. Over the following 15 years, 14 splenectomies were attempted as therapy for leukemia; none of the patients survived. In a 1908 review of 49 similar cases, Johnston reported a mortality of 87.7%.² These dismal results led to the abandonment of splenectomy for leukemia. In 1916, Kaznelson, of Prague, was the first to report good results from splenectomy in patients with thrombocytopenic purpura.

As the 20th century progressed, splenectomy became more common in direct proportion to the increase in the use of the automobile. The eventual recognition of the syndrome known as overwhelming postsplenectomy infection (OPSI) made splenic conservation an important consideration. Partial splenectomy had initially been described by the French surgeon Péan in the 19th century. This procedure received little further study until almost 100 years later, when the Brazilian surgeon Campos Cristo reevaluated Péan's technique in his report of eight trauma patients treated with partial splenectomy.³ Upadhyaya and Simpson's report on 16 children admitted for splenic trauma to The Hospital for Sick Children in Toronto between 1948 and 1955 was instrumental in establishing the validity of nonoperative treatment of splenic trauma.⁴

In late 1991 and early 1992, four groups working independently—Delaitre in Paris, Carroll in Los Angeles, Cushieri in the United Kingdom, and our group in Canada—published the first reports of laparoscopic splenectomy in patients with hematologic disorders.^{5–7} Since then, the development of operative techniques for partial laparoscopic splenectomy has tested the limits of minimally invasive surgery and encouraged clinical research into methods of simplifying the execution of the operation.^{8–10} The adoption of laparoscopic

splenectomy has led to a gradual decrease in the indications for open splenectomy; however, both procedures are still essential components of spleen surgery.

Anatomic Considerations

Most anatomy texts suggest that the splenic artery is constant in its course and branches; however, as the classic essay by Michels made clear, each spleen has its own peculiar pattern of terminal artery branches.¹¹

SPLENIC ARTERY

The celiac axis is the largest but shortest branch of the abdominal aorta: it is only 15 to 20 mm long. The celiac axis arises above the body of the pancreas and, in 82% of specimens, divides into three primary branches: the left gastric artery, which is the first branch, and the hepatic and splenic arteries, which derive from a common stem. In rare instances, the splenic artery originates directly from the aorta; even less often, a second splenic artery arises from the celiac axis. There are numerous other possible variations, in which the splenic artery may originate from the aorta, the superior mesenteric artery, the middle colic artery, the left gastric artery, the left hepatic artery, or the accessory right hepatic artery. As a rule, however, the splenic artery arises from the celiac axis to the right of the midline, which means that the aorta must be crossed to reach the spleen and that selective angiography is likely to be difficult at times. The splenic artery can take a very tortuous course, particularly in patients who are elderly or who have a longer artery.

In his study of 100 cadaver spleens, Michels divided splenic arterial geography into two types, distributed and magistral (or bundled) [see Figure 1].¹¹ In the distributed type, found in 70% of dissections, the splenic trunk is short, and six to 12 long branches enter the spleen over approximately 75% of its medial surface. The branches originate between 3 and 13 cm from the hilum [see Figure 1a]. In the bundled type, found in the remaining 30% of dissections, there is a long main splenic artery that divides near the hilum into three or four large, short terminal branches that enter the spleen over only 25 to 35% of its medial surface. These short splenic branches originate, on average, 3.5 cm from the spleen, and they reach the center of the organ as a compact bundle [see Figure 1b]. Early identification of the type of splenic blood supply present can help the surgeon estimate how difficult a particular splenectomy is likely to be. Operation on a spleen with a distributed vascular anatomy usually involves dissection of more blood vessels; however, the vessels, being spread over a wider area of the splenic hilum, are relatively easy to deal with. Operation on a spleen with a bundled-type blood supply typically involves dissection of fewer vessels; however, because the

Figure 1 Splenic vascularization. Shown are (a) the distributed type and (b) the magistral (bundled) type of splenic vascularization.

hilum is narrower and more compact, dissection and separation of the vessels are more difficult.

BRANCHES OF SPLENIC ARTERY

The splenic branches vary so markedly in length, size, and origin that no two spleens have the same anatomy. Outside the spleen, the arteries also frequently form transverse anastomoses with each other that, like most collaterals, arise at a 90° angle to the vessels involved [see Figure 1].¹² As a consequence, attempts to occlude a branch of the splenic artery by means of clips or embolization, if carried out proximal to such an anastomosis, may fail to devascularize the corresponding splenic segment. Before the splenic trunk divides, it usually gives off a few slender

branches to the tail of the pancreas. The most important of these is called the pancreatica magna (a vessel familiar to vascular radiologists); occlusion of this branch with embolic material has been reported to result in pancreatitis. Next, the splenic artery divides into two to six first and second terminal branches, and these branches undergo two further levels of division into two to 12 penultimate and ultimate branches. Segmental and subsegmental division can occur either outside or inside the spleen. The number of arteries entering the spleen ranges from six to 36. The size of the spleen does not determine the number of arteries entering it; however, the presence of notches and tubercles usually correlates well with a higher number of entering arteries.

A reasonable general scheme of splenic artery branches might include as many as seven principal branches at various division levels and in various anatomic arrangements: (1) the superior terminal artery, (2) the inferior terminal artery, (3) the medial terminal artery, (4) the short gastric arteries, (5) the left gastroepiploic artery, (6) the inferior polar artery, and (7) the superior polar artery [see Figure 2]. Veins are usually located behind the corresponding arteries, except at the ultimate level of division, where they may be either anterior or posterior.

First Terminal Division Branches

A classic study from 1917 found that 72% of specimens had three terminal branches (superior polar, superior terminal, and inferior terminal) and 28% had two; the medial terminal artery was observed in only 20% of cases.¹³ When the superior terminal artery is excessively large, the inferior terminal is rudimentary, with an added blood supply often coming from the left gastroepiploic and polar vessels.

Second Terminal Division Branches

Superior polar artery The superior polar artery is present in 65% of patients. It usually arises from the main splenic trunk (75% of cases) or the superior terminal artery (20% of cases), but, on occasion, it may originate from the inferior terminal artery or separately from the celiac axis (thus providing the spleen with a double splenic artery). In most instances, the superior polar artery gives rise to one or two short gastric branches; rarely, it gives rise to the left inferior phrenic and pancreatic rami. The presence and size of this artery appear to be correlated with tubercle formation in that it is more

prominent in spleens with large tubercles. The superior polar artery is frequently very long and slender and thus easily torn during splenectomy; accordingly, it was suggested in 1928 that ligation of splenic branches be started from the inferior pole of the spleen.¹⁴

Inferior polar artery The inferior polar artery is present in 82% of cases. As many as five collateral branches may arise from the splenic trunk, the inferior terminal artery, or, as noted, the left gastroepiploic artery. Inferior polar branches may have multiple origins, and they tend to be of smaller caliber than the superior polar artery.

Left gastroepiploic artery The left gastroepiploic artery, the most varied of the splenic branches, courses along the left side of the greater curvature in the anterior layer of the greater omentum. In 72% of cases, it arises from the splenic trunk several centimeters from its primary terminal division, and in 22% of cases, it originates from the inferior terminal artery or its branches; however, it may also originate from the middle of the splenic trunk or from the superior terminal artery. Characteristically, the left gastroepiploic artery gives off inferior polar arteries, which vary in number (ranging from one to five), size, and length. Typically, these branches are addressed first during laparoscopic splenectomy. When they are small, they can usually be controlled with the electrocautery.

Collaterals

As many as six short gastric arteries may arise from the fundus of the stomach, but, as a rule, only the one to three

Figure 2 Division of splenic artery branches. Outlined is a general scheme of the levels of division of the splenic artery branches.

that open into the superior polar artery must be ligated during laparoscopic splenectomy [see *Figure 1*].

SUSPENSORY LIGAMENTS OF SPLEEN AND TAIL OF PANCREAS

Duplications of the peritoneum form the many suspensory ligaments of the spleen [see *Figure 3*]. Medially and posteriorly, the splenorenal ligament contains the tail of the pancreas and the splenic vessels. Anteriorly, the gastrosplenic ligament contains the short gastric and gastroepiploic arteries. In the lateral approach to laparoscopic splenectomy [see *Operative Technique, below*], the splenorenal and gastrosplenic ligaments are easily distinguished, and dissection of the anatomic structures they contain is relatively simple. In the anterior approach, these two ligaments lie on top of each other, and to separate them correctly and safely requires considerable experience with splenic anatomy.

The phrenicocolic ligament courses laterally from the diaphragm to the splenic flexure of the colon; its upper portion is called the phrenicosplenic ligament. The attachment of the lower pole on the internal side is called the splenocolic ligament. Between these two structures, a horizontal shelf of areolar tissue, known as the sustentaculum lienis, is formed on which the inferior pole of the spleen rests. The sustentaculum lienis is often molded into a sac that opens cephalad and acts as a support for the lower pole. This structure, often overlooked during open procedures, is readily visible through a laparoscope. The phrenicocolic ligament, the splenocolic

ligament, and the sustentaculum lienis are usually avascular, except in patients who have portal hypertension or myeloid metaplasia.

A 1937 study found that the tail of the pancreas was in direct contact with the spleen in 30% of cadavers.¹⁵ A subsequent report confirmed this finding and added that in 73% of patients, the distance between the two structures was no more than 1 cm.¹⁶ Although a recent anatomic study based on computed tomography (CT) mapping shows slightly different measures, the message is the same.¹⁷ Care must be exercised to avoid pancreas damage with the electrocautery during dissection as well as damage with the linear stapler in the course of en masse ligation of the splenic hilum (a maneuver more easily performed via the lateral approach to laparoscopic splenectomy).

Laparoscopic Splenectomy

PREOPERATIVE EVALUATION

Currently, we consider all patients evaluated for elective splenectomy to be potential candidates for laparoscopic splenectomy. Contraindications to a laparoscopic approach include severe portal hypertension, uncorrectable coagulopathy, severe ascites, and most traumatic injuries to the spleen. Extreme splenomegaly remains a relative contraindication as well. Because most patients scheduled for laparoscopic splenectomy have hematologic disorders, they undergo the same hematologic preparation that patients scheduled for open surgery do—namely, steroids, γ -globulins, fresh frozen plasma, cryoprecipitate, or platelets when required. Ultrasonography is performed to determine the size of the spleen. Spleen size is expressed in terms of the maximum interpole length (i.e., the length of the line joining the two organ poles) and is generally classified into three categories: (1) normal spleen size (< 11 cm), (2) moderate splenomegaly (11 to 20 cm), and (3) severe splenomegaly (> 20 cm).¹⁸ Because extremely large spleens present special technical problems that test the current limits of laparoscopic surgery, we make use of a fourth category for spleens longer than 30 cm or heavier than 3 kg, which we call megaspleens [see *Table 1*]. The ultrasonographer is also asked to try to identify any accessory spleens that may be present. CT is done when there is doubt about the exactness of the ultrasonographic measurement; such measurement is sometimes inaccurate at the upper pole and with spleens longer than 16 cm.

Patients receive thorough counseling about the consequences of the asplenic state. Polyvalent pneumococcal vaccine is administered at least 2 weeks before operation in all cases with boosters every 5 to 10 years as dictated by the levels of antibody titers;

Figure 3 Suspensory ligaments of the spleen. Depicted are the suspensory ligaments of the spleen.

Table 1 Classification of Spleens According to Spleen Length*

Spleen Class	Spleen Length (cm)
Normal-size spleen	7–11
Moderate splenomegaly	12–20
Massive splenomegaly	21–30
Megaspleen	> 30

*Spleen length is defined as interpole length, measured along a straight line connecting the two poles.

preoperative vaccination against *Haemophilus influenzae* type B and meningococcus serogroup C is also given. Annual influenza vaccination should also be suggested. Heparin prophylaxis for thrombophlebitis is administered according to standard guidelines provided that there is no hematologic contraindication. Nonsteroidal antiinflammatory drugs (NSAIDs) are often given orally before operation to minimize postoperative pain; however, on empirical grounds, NSAIDs are not used when heparin prophylaxis is employed. Platelets are rarely, if ever, required when laparoscopic splenectomy is performed for idiopathic (immune) thrombocytopenic purpura (ITP).¹⁹

OPERATIVE PLANNING

Laparoscopic splenectomy presents special problems, such as the necessity of dealing with a fragile and richly vascularized organ that is situated close to the stomach, the colon, and the pancreas and the difficulty of devising an extraction strategy that is compatible with proper histologic confirmation of the pathologic process while maintaining the advantages of minimal access surgery. For successful performance of laparoscopic splenectomy, detailed knowledge of both splenic anatomy and potential complications is essential. The operative strategy is largely determined by the anatomic features, which, as noted [see *Anatomic Considerations, above*], may vary considerably from patient to patient.²⁰

OPERATIVE TECHNIQUE

Lateral Approach

This approach was first described in connection with laparoscopic adrenalectomy and is currently used for most laparoscopic splenectomies.²¹ At present, the only indication for the anterior approach to laparoscopic splenectomy is the presence of massive splenomegaly, a megaspleen, or when a secondary procedure is required, especially in pediatric patients.²² Typically, this alternative approach is taken when a spleen reaches or exceeds 23 cm in length or 3 kg in weight.

Step 1: placement of trocars The patient is placed in the right lateral decubitus position, much as he or she would be for a left-side posterolateral thoracotomy. The operating table is flexed and the kidney bolster raised to increase the distance between the lower rib and the iliac crest. Usually, four 12 mm trocars are used around the costal margin so that the camera, the clip applier, and the linear stapler can be interchanged with maximum flexibility [see *Figure 4*]. The trocars must be far enough apart to permit good working angles. Some advantage may be gained from tilting the patient slightly backward; this step gives the operating team more freedom in moving the instruments placed along the left costal margins, especially during lifting movements, when it is easy for instrument handles to touch the operating table. For the same reason, it is also advisable to place the anterior or abdominal side of the patient closer to the edge of the operating table.

A local anesthetic is infiltrated into the skin at the midpoint of the anterior costal margin, and a 12 mm incision is made. The first trocar is inserted under direct vision, and a symmetrical 15 mm Hg pneumoperitoneum is created. The locations of the remaining trocars are determined by considering the anatomic configuration in relation to the size of the spleen

to be excised. In most cases, the fourth posterior trocar cannot be inserted until the splenic flexure of the colon has been mobilized. Accordingly, the procedure is usually started with three trocars in place. In the end, three trocars are placed anteriorly along the costal margin and one is located in the left flank.

Troubleshooting After years of using the Veress needle, we now prefer the open method of inserting the first trocar. It is true that use of the Veress needle is, for the most part, safe; however, the small number of catastrophic complications that occur with blind methods of first trocar insertion are more and more difficult to justify. Admittedly, these complications are infrequent; thus, it is unlikely that even a large randomized trial would be able to show any significant differences between various methods of first trocar insertion. Nevertheless, even though complications occur with the open method of first trocar insertion as well, they are very uncommon and tend to be limited to trauma to the intestine or the omental blood vessels; they do not have the same serious consequences as the major vessel injury that may arise from blind trocar insertion.

Trocar placements differing from the ones we describe may be considered. More experienced surgeons (or those simply wishing to make the procedure easier) may choose to replace one or two 12 mm trocars with 5 mm trocars [see *Figure 5a*]. The procedure can also be performed with only three trocars. In leaner patients, one of the trocars can be inserted into the umbilicus to gain a cosmetic advantage. The advent of needlescopic techniques has made it possible to replace some of the 5 and 12 mm trocars with 3 mm trocars. The ultimate (i.e., least invasive) technique, usually reserved for lean patients with ITP and normal-size spleens, involves one 12 mm trocar placed in the umbilicus and two 3 mm trocars placed subcostally [see *Figure 5b*]. This approach requires two different camera-laparoscope setups so that a 3 mm laparoscope can be interchanged with a 10 mm laparoscope as necessary to permit application of clips or staplers through the umbilical incision once the dissection is completed. This can also be achieved with a single camera setup using a sterile clip-on camera sleeve with an acrylic window. The specimen is then retrieved through the umbilicus. Because the use of 3 mm laparoscopes is accompanied by a decrease in available intra-abdominal light and focal width, a meticulously bloodless field and sophisticated surgical judgment are critical for successful performance of needlescopic splenectomy.

Step 2: search for and retrieval of accessory spleens

The camera is inserted, and the stomach is retracted medially to expose the spleen. Then a fairly standard sequence is followed. A thorough search is then made for accessory spleens. To maximize retrieval, all known locations of accessory spleens should be carefully explored [see *Figure 6*]. Any accessory spleens found should be removed immediately; they are considerably harder to locate once the spleen is removed and the field is stained with blood.

Troubleshooting It is especially important to retrieve accessory spleens from patients with ITP, in whom the presence of overlooked accessory spleens has been associated with recurrence of the disease. Remedial operation for excision of missed accessory spleens has been reported to bring remission of recurrent disease; such an operation can be performed

Figure 4 Laparoscopic splenectomy: lateral approach. Shown is standard trocar placement. Four trocars are used. In most cases, the procedure is begun without the posterior trocar in place.

Figure 5 Laparoscopic splenectomy: lateral approach. Shown are alternative trocar placements. (a) In some patients (e.g., thin patients with normal-size spleens), a 12 mm trocar may be placed in the umbilicus to gain a cosmetic advantage, and most of the other trocars may be downsized to 5 mm. (b) In the needlescopic approach, only three trocars are placed: a 12 mm trocar in the umbilicus and two 3 mm subcostal trocars. Two camera-laparoscope setups (3 and 10 mm) are required.

Figure 6 Laparoscopic splenectomy: lateral approach. (a) Accessory spleens are known to occur at specific sites. (b) Shown is an accessory spleen.

laparoscopically, with some authors suggesting the use of a handheld gamma probe and/or CT-guided methylene blue injection for identifying retained accessory spleens.²³ The overall retrieval rate for accessory spleens should fall between 15 and 30%.

Splenic activity has been demonstrated after open and laparoscopic splenectomy for trauma and hematologic disorders^{24,25}; accordingly, it is advisable to wash out and recover all splenic fragments resulting from intraoperative trauma at the end of the procedure. This step is particularly important for patients with ITP, in whom intraoperative trauma to the spleen is thought to contribute to postoperative scan-detectable splenic activity.

Step 3: control of vessels at lower pole, demonstration of “splenic tent,” and incision of phrenicocolic ligament The splenic flexure is partially mobilized by incising the splenocolic ligament, the lower part of the phrenicocolic ligament, and the sustentaculum lienis. The incision is carried slightly into the left side of the gastrocolic ligament. This step affords access to the gastrosplenic ligament, which can then be readily separated from the splenorenal ligament to create what looks like a tent. This maneuver cannot be accomplished in all cases, but when it can be done, it simplifies the procedure considerably. The walls of this so-called splenic tent are made of the gastrosplenic ligament on the left and the splenorenal ligament on the right, and the floor is made up of the stomach. In fact, this maneuver opens the lesser sac in its lateral portion (a point that is better demonstrated with gentle upward retraction of the splenic tip) [see Figure 7].

Figure 7 Laparoscopic splenectomy: lateral approach. The so-called splenic tent is formed by the gastrosplenic and splenorenal ligaments laterally and the stomach below.

The branches of the left gastroepiploic artery are controlled with the electrocautery or with clips, depending on the size of the branches. The avascular portion of the gastrosplenic ligament, situated between the gastroepiploic artery (and its branches) and the short gastric vessels, is then incised sufficiently to expose the hilar structures in the splenorenal ligament. To accomplish this, the lower pole is gently elevated; in this position, the spleen almost retracts itself as it naturally

falls toward the left lobe of the liver. At this point, the surgeon can usually assess the geography of the hilum and determine the degree of difficulty of the operation. The fourth trocar, if needed, is then placed posteriorly under direct vision, with care taken to avoid the left kidney. Caution must also be exercised in placing the trocars situated immediately anterior and posterior to the iliac crest. The iliac crest can impede movement and hinder upward mobilization of structures if the trocars are placed over it rather than in front of or behind it [see Figure 8].

Finally, the phrenicocolic ligament is incised all the way to the left crus of the diaphragm, either with a monopolar electrocautery with an L hook or with scissors. A small portion of the ligament is left to keep the spleen suspended and facilitate subsequent bagging. The phrenicocolic ligament is avascular except in patients with portal hypertension or myeloproliferative disorders (e.g., myeloid metaplasia). Leaving 1 to 2 cm of ligament all along the spleen side facilitates retraction and handling of the spleen with instruments.

Troubleshooting Remarkably few instruments are needed for laparoscopic splenectomy: most of the operation is done with three reusable instruments. A dolphin-nose 5 mm atraumatic grasper is used to elevate and hold the spleen. It is also used to separate tissue planes and vessels with blunt dissection because its atraumatic tip is easily insinuated between tissue planes. A gently curved 5 mm fine-tip dissector (Crile or Maryland) and a 10 mm 90° right-angle dissector are the only other tools required for cost-efficient dissection.

When a powered instrument is called for, we use a monopolar electrocautery with an L hook or a gently curved scissors. Alternatively, an ultrasonic dissector or a tissue-welding device may be used, albeit at a much higher cost. We tend to limit the use of these very elegant technologies to cases where some operative difficulty is anticipated.

Step 4: dealing with splenic hilum and tailoring operative strategy to anatomy It is advisable to base one's operative strategy on the specific splenic anatomy. If a

Figure 8 Laparoscopic splenectomy: lateral approach. Shown is the recommended trocar placement around the iliac crest.

distributed anatomy is present, the splenic branches are usually dissected and clipped. This is not only the least costly approach but also the simplest, in that the vessels are spread over a wider area of the splenic hilum and are easier to dissect and separate [see Figure 9].

A bundled anatomy lends itself more to a single use of the linear stapler provided that the tail of the pancreas is identified and dissected away when required. When possible, a window is created above the hilar pedicle in the splenorenal ligament so that all structures can be included within the markings of the linear stapler under direct vision [see Figure 10]. The angles provided by the various trocars make this maneuver much easier via the lateral approach than via the anterior approach. Dissection continues with individual dissection and clipping of the short gastric vessels; occasionally, these vessels can also be taken en masse with the linear stapler. We rarely have had to use intracorporeal sutures in this setting, except occasionally to control a short gastric vessel too short to be clipped safely. This portion of the operation is performed while the spleen is hanging from the upper portion of the phrenicocolic ligament, which has not yet been entirely cut.

Troubleshooting At this point in the procedure, experience in designing the operative strategy pays off in reduced operating time. Because of the many variations in size, shape, vascular patterns, and relations to adjacent organs, spleens are almost as individual as fingerprints. Accordingly, an experienced spleen surgeon learns to keep an open mind with regard to operative strategy and must be able to call on a wide range of skills to facilitate the procedure.

The surgeon should start by looking at the internal surface of the spleen. If the splenic vessels cover more than 75% of the internal surface (as is the case in 70% of patients), a distributed anatomy is present. With a distributed vascular anatomy, the vessels tend to be easier to dissect and isolate and thus can be readily (and cost-effectively) controlled with clips. On the other hand, if the splenic vessels entering the spleen cover only 25 to 35% of the inner surface of the hilum (30% of patients), the pattern is bundled. With a bundled vascular anatomy, the vessels, being fewer and closer together, can usually be controlled with a single application of the vascular stapler across the hilum provided that the tail of the pancreas can be protected.

Experienced surgeons also become very clever in using the position of the operating table to their advantage. The reverse Trendelenburg position (Fowler) allows the spleen to move away from the diaphragm in cases where the dissection of the upper pole is made more difficult by adhesions from previous surgery, large spleens, obesity, or previous infarctions of the spleen. With the patient stabilized by a bean bag, changing the degree of the lateral position is also useful. The surgeon learns to move the spleen back and forth so that it can be observed from an anterior and posterior perspective. The surgeon can then decide whether the approach to the splenic vessels is more appropriate from the front or the back.

Step 5: extraction of spleen A medium-size or large heavy-duty plastic freezer bag, of the sort commercially available in grocery stores, is used to bag the spleen. This bag is sterilized and folded and then introduced into the abdominal cavity through one of the 12 mm trocars [see Figure 11]. The

Figure 9 Laparoscopic splenectomy: lateral approach. (a, b) Clipping is well suited to controlling short gastric or gastroepiploic vessels. It is also appropriate for distributed-type splenic vasculatures, in which more splenic vessels are spread over a wider area of the hilum.

bag is unfolded and the spleen slipped inside to prevent splenosis during the subsequent manipulations. Grasping forceps are used to hold the two rigid edges of the bag and to effect partial closure. Bagging is facilitated by preserving the upper portion of the phrenicocolic ligament. After final section of the phrenicocolic ligament and any diaphragmatic adhesions present, extraction is performed through one of the anterior port sites. Extraction through a posterior site is more difficult because of the thickness of the muscle mass; usually, the incision must be opened, and more muscle must be fulgurated than is desirable.

The subcostal or umbilical incision through which extraction is to take place is extended slightly. Grasping forceps are inserted through the extraction incision to hold the edges of the bag inside the abdomen. Gentle traction on the bag from outside brings the spleen close to the peritoneal surface of the umbilical incision and then out of the wound [see Figure 12]. Specimen retrieval bags have been developed that can accommodate a normal-size spleen and thus make bagging much easier, but they are costly.

A biopsy specimen of a size suitable for pathologic identification is obtained by incising the splenic tip. The spleen is then fragmented with finger fracture, and the resulting blood is suctioned. The remaining stromal tissue of the spleen is then extracted through the small incision, hemostasis is again verified, and all trocars are removed. No drains are used. The incisions are closed with absorbable sutures and paper strips.

Troubleshooting The freezer bags can be more easily introduced into the abdomen if they are pulled in rather than pushed in [see Figure 11]. This may be accomplished by bringing out a 5 mm toothed grasper through the introduction trocar from another properly angled trocar, grasping the specimen bag, and pulling the bag back down through the trocar. A laparoscopic hernia mesh introducer may also be used.

Slipping the spleen into a freezer bag is also an acquired skill that takes some time to master. It is an important skill that is useful in many other instances where specimen retrieval

is needed (e.g., in procedures involving the gallbladder, the appendix, the adrenal glands, or the colon). In addition, it is highly cost-effective in that these commercially available bags cost only a few cents each. Admittedly, laparoscopic retrieval bags are easier to use, but their substantially higher cost can become a factor in a busy minimally invasive surgery unit. A suction machine (–70 mm Hg) and a custom-made sharp beveled 10 mm cannula can be used to suction splenic tissue from the plastic retrieval bag. When extraction is done with the use of any type of forceps or graspers, surgeons have noticed that initially the extracted spleen fragments tend to be small and tedious to extract. As the extraction proceeds, the fragments get bigger and easier to extract. Definitely, imagination and patience are required for this part of the procedure.

Anterior Approach

The anterior approach is seldom used nowadays; however, it remains the preferable approach in some patients with massive splenomegaly (21 to 30 cm long) and all patients with megaspleens (> 30 cm or > 3 kg) with the aid of hand-assisted devices [see Special Considerations, Hand-Assisted Laparoscopic Splenectomy, below]. Very large spleens are extremely heavy and difficult to manipulate with laparoscopic instruments, and it is complicated to lift them so as to gain access to the phrenicocolic ligament posteriorly. The anterior approach can also be considered if another procedure (e.g., cholecystectomy) is being contemplated; alternatively, in this situation, the lateral approach can be used, and the patient can be repositioned for the secondary procedure.

Step 1: placement of trocars Under general anesthesia, the patient is placed in a modified lithotomy position to allow the surgeon to operate between the patient's legs and to allow the assistants to stand on each side of the patient. The procedure is performed through five trocars in the upper abdomen [see Figure 13], with the patient in a steep Fowler position with left-side elevation. A 12 mm trocar is introduced through an

Figure 10 Laparoscopic splenectomy: lateral approach. (a through c) Stapling is particularly well suited to the compact hilum found in the magistral-type distribution of splenic vessels. As shown, all of the vascular structures are within the stapler markers, and the tail of the pancreas is well protected.

umbilical incision, and a 10 mm laparoscope (0° or 30°) is connected to a video system. A 12 mm trocar is placed in each upper quadrant, and two 5 mm trocars are inserted close to the rib margin on the left and right sides of the abdomen.

Figure 11 Laparoscopic splenectomy: lateral approach. Illustrated is the introduction of a sterile freezer bag for specimen extraction via the pull method. A toothed grasper is passed across the abdomen between two trocars and brought out through the 12 mm umbilical trocar site. This grasper is used to pull the extraction bag back into the abdomen.

Alternatively, trocars can be deployed in a semicircle away from the left upper quadrant. Trocar sites are carefully selected to optimize working angles. The 12 mm ports are used to allow introduction of clip appliers, staplers, or the laparoscope from a variety of angles as needed.

Troubleshooting With increasing experience, we find that we prefer to do as many laparoscopic splenectomies as possible via the lateral approach because it is so much easier, even with spleens that are longer than 20 cm and are readily palpable. The decision is arbitrarily made on the basis of estimated available working space. If the spleen comes too close to the iliac crest or the midline, the anterior approach should be taken instead.

Figure 12 Laparoscopic splenectomy: lateral approach. Shown is the position of the specimen bag before finger fragmentation or pulp suction.

Figure 13 Laparoscopic splenectomy: anterior approach. Shown is standard trocar placement. The umbilical site is used for the camera. The remaining trocars are placed in the left and right upper quadrants, the epigastrium, and the right subcostal region. Depending on the size of the spleen, the trocars can also be disposed in a semicircle away from the left upper quadrant.

Step 2: isolation of lower pole and control of blood supply The left hepatic lobe is retracted, and the stomach is retracted medially to expose the spleen. Accessory spleens are searched for, and the phrenicocolic ligament, the splenocolic ligament, and the sustentaculum lienis are incised near the lower pole with an electrocautery and a hook probe or with scissors. Vascular adhesions—frequently found on the medial side of the spleen—are cauterized. They are also called *criminal folds* for their tendency to be avulsed off the spleen during dissection and cause nuisance bleeding from the capsular injury. The gastrosplenic ligament is carefully dissected close to the spleen, and the left gastroepiploic vessels are ligated one by one with metallic clips or, if small, simply cauterized. The upper and lower poles of the spleen are gently lifted with one or both palpators (placed through the 5 mm ports) to expose the splenic hilum and the tail of the pancreas within the splenorenal ligament, thereby facilitating individual dissection and clipping of all the branches of the splenic artery and vein close to the spleen. The short gastric vessels are then identified and ligated with clips or, occasionally, with staples. No sutures are used. Alternatively, the splenic artery itself can be isolated and clipped within the lesser sac before extensive dissection of the lower pole and suspensory ligaments.

Because of the segmental and terminal distribution of splenic arteries, it is easy to determine the devascularized

portions of the spleen: these segments exhibit a characteristic grayish color, whereas the vascularized segments retain a pinkish hue. When the organ is completely isolated, it is left in its natural cavity, and hemostasis is verified.

Troubleshooting If one elects first to clip the splenic artery within the lesser sac, a few precautions must be taken. First, the clipping must be done distal to the pancreatic magna to prevent pancreatic injury. Second, one must make sure that the splenic artery proper is clipped, not one of its branches (e.g., the superior terminal branch). This is an easy mistake to commit with the distributed type of splenic vasculature [see Figure 1] because the splenic artery itself is short and the branches can take off very early. Third, one must always keep in mind the possibility of an anastomotic branch between the major splenic branches, as described by Testut.¹² Should a major terminal branch be clipped rather than the splenic artery proper, there will be no spleen ischemia if such an anastomosis is present [see Figure 1].

Yet another challenge posed by the anterior approach is that if bleeding occurs, the blood tends to pool in the area of the hilum and obscure vision even more, whereas in the lateral approach, the blood tends to flow away from the operative field. One quickly learns that there is a steep price to pay for cutting corners during the dissection. The dissection must be meticulous, especially behind branches of the splenic vein.

Step 3: extraction of spleen Given that the anterior approach is now used only in cases of massive splenomegaly or megaspleen, bagging can be problematic. The largest commercially available freezer bag we have seen measures 27 by 28 cm, and the largest spleen we have been able to bag in one of them was 24 cm long. Furthermore, an accessory extraction incision is often required; a Pfannenstiel incision gives better cosmetic results, but a left lower quadrant incision can also be used. Hand-assisted devices are used with increasing frequency in laparoscopic removal of large spleens [see Special Considerations, Hand-Assisted Laparoscopic Splenectomy, *below*] and are becoming the preferred method for dealing with massive splenomegaly laparoscopically.

Laparoscopic Partial Splenectomy

Concern regarding the risk of OPSI has encouraged the practice of preserving splenic tissue and function whenever possible. For this reason, partial splenectomy has occasionally been indicated for treatment of benign tumors of the spleen and for excision of cystic lesions.²⁶ Its use has been described in connection with the management of type I Gaucher disease, cholesteryl ester storage disease, chronic myelogenous leukemia, single metastasis, thalassemia major, staging of Hodgkin disease, and spherocytosis.^{27–30} It has also been suggested for some cystic fibrosis patients with hypersplenism. Partial splenectomy is an option in the management of splenic trauma when the patient's condition is stable enough to permit the meticulous dissection required for the operation.^{31,32}

Like standard laparoscopic splenectomy, laparoscopic partial splenectomy is performed with the patient in the right lateral decubitus position. Trocar placement is similar as well. The splenocolic ligament and the lower part of the phrenicocolic ligament are incised to permit mobilization of the lower pole of the spleen. If the lower portion of the spleen is to be excised, branches of the gastropiploic vessels supplying the lower pole are dissected and clipped close to the parenchyma. An appropriate number of penultimate branches of the inferior polar artery are then taken in such a way as to create a clear line of demarcation between normal spleen and devascularized spleen. This process is continued until the desired number of splenic segments are devascularized.

Next, a standard monopolar electrocautery is used to score the splenic capsule circumferentially, with care taken to ensure that a 5 mm rim of devascularized splenic tissue remains in situ; this is the most important technical point for this procedure [see *Figure 14*]. The incision is then carried into the splenic pulp. Atraumatic intestinal graspers are also used to fracture the splenic pulp in a bloodless fashion. The laparoscopic L hook and scissors provide excellent hemostatic control with simple spot coagulation or spray current in the coagulation mode. No drains are used. Alternative methods of hemostasis have also been used, including argon beam coagulators, ultrasonic shears, linear staplers, bipolar tissue welding instruments, and radiofrequency ablation probes.²⁹

Once the spleen has been allowed to demarcate, resection is remarkably bloodless, provided that the 5 mm rim of ischemic tissue is left in place. Complete control of the splenic artery is not required before splenic separation, because division occurs in an ischemic segment of spleen.⁹ The feasibility of leaving portions of ischemic spleen in situ has been demonstrated in a

large prospective, randomized trial involving partial splenic embolization as primary treatment of hematologic disorders.³³

If the superior pole is to be removed, the phrenicocolic ligament must be incised almost entirely so that the spleen can be easily mobilized and the proper exposure achieved. The short gastric branches are taken first, along with the desired number of superior polar artery branches.

Laparoscopic partial splenectomy can be performed either with or without the aid of selective preoperative arterial embolization (see below). Radiologists are capable of cannulating the desired segmental splenic arterial branch and embolizing the segment that is to be resected. This is well documented in the recent trauma literature.³⁴

Preoperative Splenic Artery Embolization

Preoperative splenic artery embolization is used as an adjuvant in a few patients to make laparoscopic splenectomy possible and to reduce blood loss. Although it is now infrequently used, it remains a useful tool in the armamentarium of spleen surgeons.³⁵

Generally speaking, the technique involves embolization of the spleen with coils placed proximally in the splenic artery and absorbable gelatin sponges and small coils placed distally in each splenic arterial branch (the double embolization technique), with care taken to spare vessels supplying the tail of the pancreas [see *Figure 15*].

The procedure is ended when it is estimated radiologically that 80% or more of the splenic tissue has been successfully embolized. In most cases, successful embolization is achieved with both proximal and distal emboli; in a minority of cases, it is achieved with proximal emboli alone or with distal emboli alone.³⁵

Troubleshooting Preoperative splenic artery embolization is safe provided that two main principles are adhered to. First, embolization must be done distal to the pancreatica magna to avoid damaging the pancreas. Second, neither microspheres nor absorbable gelatin powder should be used, because particles of this small size may migrate to unintended target organ capillaries and cause tissue necrosis; only coils and absorbable gelatin sponge fragments should be used.

POSTOPERATIVE CARE

Postoperative care for patients who have undergone laparoscopic splenectomy is usually simple. The nasogastric tube inserted after induction of general anesthesia is removed either in the recovery room, once stomach emptying has been verified, or the next morning, depending on the duration and the degree of technical difficulty of the procedure. The urinary catheter is usually removed before the patient leaves the recovery room. The patient is allowed to drink clear fluids on the morning after the operation; when clear fluids are well tolerated, the patient is allowed to proceed to a diet of his or her choice.

A proper pain control process is started before the procedure. If the patient has no history of ulcer or dyspepsia, celecoxib, a cyclooxygenase-2 NSAID, is started preoperatively because there is little effect on platelet function. Alternatively, 50 mg of ketorolac can be given 30 minutes before the end of the procedure. All trocar sites are infiltrated with local anesthetic at the start of surgery. This is done to prevent the establishment of peripheral and central sensitization (“wind-up”), conditions that

Figure 14 Laparoscopic splenectomy: partial splenectomy. (a, b) The splenic capsule is scored with the monopolar cautery, and a 5 mm margin of devitalized tissue is left. (c) The splenic pulp is fractured with an atraumatic grasper. The electrocautery with the L hook is also used to control parenchymal bleeding. (d) Shown is the cut surface of the spleen after transection. The operative field remains remarkably dry.

Figure 15 Laparoscopic splenectomy: splenic artery embolization. Shown are splenic angiograms of a patient with thrombotic thrombocytopenic purpura before (left) and after (right) splenic artery embolization with 3, 5, and 7 cm coils and absorbable gelatin sponge fragments.

promote an increased response to pain stimuli. Ketorolac or another NSAID is administered regularly in the postoperative period following the “first in last out” principle of NSAID administration for pain control. NSAIDs have been shown to have a 30 to 50% opioid-sparing effect. Morphine-based patient-controlled analgesia is used the first night after surgery. The following morning, acetaminophen and NSAIDs usually suffice. Oral hydromorphone hydrochloride, 2 to 4 mg, is reserved for breakthrough pain. A prescription for these three oral drugs is given on discharge. Because of its adverse effects of nausea, vomiting, abdominal fullness, and constipation, codeine is avoided. Furthermore, increased reports of codeine intoxication associated with ultrarapid CYP2D6 metabolism make it a poor choice.

Patients receiving intravenous (IV) cortisone are given oral steroids on postoperative day 1 after an overlap IV injection; thereafter, steroids are gradually tapered. Patients are allowed to shower 12 hours after surgery and are advised to keep the paper strips covering the trocar incisions in place for 7 to 10 days. No drains are used. No limitations are imposed on

physical activity, and patients are allowed to tailor their activities to their degree of asthenia or discomfort. An exception is made for patients with partial laparoscopic splenectomy where empirically they are asked to refrain from strenuous activity for a month.

COMPLICATIONS

Postoperative complications directly related to splenectomy include intraoperative and postoperative hemorrhage; left lower lobe atelectasis and pneumonia; left pleural effusion; subphrenic collection; iatrogenic pancreatic, gastric, and colonic injury; venous thrombosis; and overwhelming post-splenectomy sepsis.^{31,36–38}

Successful laparoscopic splenectomy depends to a large extent on proper preparation. Recognition of anatomic elements and their arrangement is paramount. As with other laparoscopic procedures, the keys are avoiding complications and minimizing technical misadventures. Vascular structures should be cleanly isolated and dissected from surrounding fat; they then can usually be controlled with two clips proximally and distally. Staplers should be used with care and should not be applied blindly. The stapler tip should be clearly seen to be free of tissue before it is closed; otherwise, hemorrhage from partial section of a major splenic branch might occur after the instrument is released. Blind application of the stapler may also result in damage to the tail of the pancreas, which often lies in close proximity to the inner surface of the spleen. If both clips and a linear stapler are used, it is vital to prevent interposition of clips in the staple line, which will cause the stapler to misfire and possibly to jam.

Improper use of the electrocautery during the procedure can cause iatrogenic injury to the stomach, the colon, or the pancreas. In a smoke-filled environment, where controlling vessels is difficult and time consuming, blind fulguration of fat in the hilum can lead to bleeding. Structures close to the lower pole in the gastocolic ligament can be approached more aggressively, but not those in the hilum. To prevent arcing and spot necrosis, which may result in delayed perforation and sepsis, the instrument should be activated only in proximity to the target organ.

The assistants also play an important role in preventing complications. All instruments, including those handled by assistants, should be moved under direct vision. Especially in the anterior approach, retraction of the liver and stomach and elevation of the spleen require constant concentration if lacerations and subsequent hemorrhage or perforation are to be avoided.

SPECIAL CONSIDERATIONS

Extraction of Specimens

Spleens removed via the anterior approach are extracted through the umbilical trocar site after finger fragmentation in a plastic bag. It is rarely necessary to enlarge the umbilical incision to more than 2 or 3 cm. When the lateral approach is used, extraction is more easily performed through one of the ports situated anteriorly. This extraction site also requires little or no enlargement. On occasion, for a spleen longer than 20 cm, a 7.5 to 10 cm Pfannenstiel incision is made, and the operator's forearm is introduced into the abdomen to deliver the spleen into the pelvis for extraction in large fragments under direct vision.³⁹ The abdomen is copiously irrigated before closure.

Special mention should be made of extraction of the splenic specimen from patients with malignant disease. If lymphoma or Hodgkin disease is suspected, neither preoperative splenic artery embolization nor finger fragmentation in a plastic bag should be performed, for fear of making the histologic diagnosis difficult. Extraction of intact spleens through a small left subcostal or median incision has also been employed when preservation of tissue architecture is required. Alternatively, a port site may be slightly enlarged, and a knife or Mayo scissors may be used to furnish the pathologist with intact specimen pieces of various sizes. The various techniques of fragmentation and extraction of splenic tissue during laparoscopic splenectomy should be discussed and agreed on with the pathologist ahead of time to ensure that proper pathologic diagnoses are not compromised by either necrotic tissue (in the case of preoperative splenic artery embolization) or altered tissue architecture (in the case of finger fragmentation), especially if malignancy is suspected but not proved. In practice, however, we have found that the diagnosis is made preoperatively in more than 90% of patients with benign and malignant hematologic disease; hence, the issue rarely arises.

Hand-Assisted Laparoscopic Splenectomy

The term *hand-assisted laparoscopic surgery* refers to laparoscopic procedures performed with the aid of a plastic device inserted in a 7.5 to 10 cm wound. This plastic hand port consists of a sealed cuff that enables a hand to be inserted into and withdrawn from the abdomen without loss of pneumoperitoneum during the operation; in this way, the surgeon regains some of the tactile feedback lost in conventional laparoscopic surgery [see Figure 16]. A number of different models have been developed, some of them quite expensive. Most use either an inflatable sleeve clipped to an O-ring,

Figure 16 Laparoscopic splenectomy: hand assisted. Shown is the use of a hand port in the left lower quadrant to facilitate laparoscopic splenectomy in a patient with a large spleen.

a spiral inflatable valve, or a flap valve to maintain pneumoperitoneum.

The optimal placement of the incision for a hand-assisted laparoscopic splenectomy remains a subject of debate: recommended locations have included the upper midline, the right upper quadrant, the left iliac fossa, and, for very large spleens, the Pfannenstiel position. Whether the surgeon is left-handed or right-handed plays a role; most surgeons agree that the nondominant hand should be used in the device.

There are obvious advantages and drawbacks to hand-assisted laparoscopic splenectomy. The most apparent disadvantage is the cosmetic cost of a longer abdominal incision (except when a Pfannenstiel incision is employed). More generally, the use of a longer incision would seem to be at odds with the current trend toward developing surgical techniques that reduce surgical trauma as much as possible. Nevertheless, comparative studies of splenectomy in patients with large spleens (> 700 g) seem to indicate that, for the most part, the hand-assisted approach yields outcomes similar to those of conventional laparoscopic splenectomy.⁴⁰

Although the precise role of hand-assisted laparoscopic splenectomy remains to be defined, this technique has an increasing place in the surgical management of patients with large spleens. In addition, the hand-assisted approach may be a valuable aid for surgeons who have not yet completed the learning curve for conventional laparoscopic splenectomy. Finally, this technique may render preoperative splenic embolization unnecessary for most very large spleens.¹⁹

Postoperative Splenic and Portal Vein Thrombosis

An increasing number of reports in the literature seem to indicate that thrombosis of the portal vein and its branches may have been underreported. This complication is important because of its potential lethality. What confuses the issue is the difference in reported incidence between retrospective (0.87 to 13.5%) and prospective (8.3 to 52%) studies in which all patients underwent postoperative imaging. Furthermore, the identification of asymptomatic patients in 25 to 38% of cases complicates management decisions. There also seems to be a difference in the clinical significance between thrombosis of the splenic vein stump, the portal vein, the superior mesenteric vein, and secondary branches of these vessels. One report suggests a higher incidence in the laparoscopic setting. Most authors agree that malignancy, especially of myeloid origin, and spleen size are independent risk factors, although the condition has been reported after splenectomy for any condition.

Although symptoms are often vague (abdominal pain, nausea, fever, ileus, diarrhea, jaundice, anorexia, ascites), the index of suspicion should be high. Once diagnosed, prompt anticoagulation therapy can prove lifesaving. More studies are needed to help determine who needs prospective imaging postoperatively, what thrombosed vessel needs more aggressive therapy, and which of the asymptomatic patients should be treated. Guidance is also needed as to the duration and type of treatment when the complication arises.^{41,42}

Overwhelming Postsplenectomy Infection

Splenectomy results in reduced clearance of extracellular (bacteria) or intracellular (malaria) particulate antigen, impaired phagocytosis, and decreased levels of properdin

and tuftsin, a tetrapeptide produced by enzymatic cleavage of the Fc domain of the heavy chain of immunoglobulin G produced mainly in the spleen. Splenectomized patients are more susceptible to sepsis caused by certain bacteria and, occasionally, protozoa, and these infections can be fulminant. OPSI is one of the few conditions where circulating or intra-leukocytic bacteria can be found in the peripheral blood or buffy coat film.⁴³

Therefore, any clinical suggestion of infection needs to be taken seriously in the splenectomized patients. From a few nonspecific symptoms, patients can rapidly progress quickly to septic shock, disseminated intravascular coagulation, and multiple organ failure.⁴⁴

The most common organism remains *Streptococcus pneumoniae* in 50 to 90% of isolates. Others include *H. influenzae* type B, *Streptococcus* type B, *Staphylococcus aureus*, *Salmonella*, *Escherichia coli*, *Campylobacter jejuni*, and, rarely, *Pseudomonas aeruginosa*.⁴³

Despite the voluminous literature, the true incidence of OPSI, its nature, the risk in various age groups, and the role of underlying conditions leading to splenectomy all remain unsettled. The incidence of infection appears highest in the first 2 years after surgery even if some controversy still exists as to whether the rate of OPSI decreases over time. Cases of fulminating infection have been reported more than 20 years after splenectomy. Reasonable estimates of the incidence of OPSI derived from cohort studies vary from 0.23 to 0.42% per year, with a lifetime risk of 5%. The risk is higher in children; in patients splenectomized for hematologic illnesses, especially malignancy, thalassemia major, and sickle cell disease; and patients with an immunocompromised status. The lowest infection and mortality have been observed in patients splenectomized for trauma, immune thrombocytopenic purpura (ITP), and spherocytosis and incidentally to other operations, such as gastrectomy. Over half of first infections occur in patients under 15 years of age. The mortality from OPSI is high (38 to 69%).^{43,45–47}

Proper vaccination against *Pneumococcus*, *Haemophilus*, and *Meningococcus*, as described in the preoperative preparation section of this text, should be adhered to. Most hospitals now have a vaccination clinic for splenectomized patients offered by infection control departments. Annual influenza vaccination should also be suggested. Other important measures include giving patients a 5-day supply of standby antibiotics to be taken at the first sign of infection even before consulting a physician. Many suggest covering dental procedures. Patients should also wear a medical bracelet or carry a medical alert card. Patients should be aware of the danger of infection from human or animal bites, and those traveling to malaria-endemic countries should avoid mosquito bites and take appropriate antimalarial prophylaxis.

The question of prophylactic antibiotics is more controversial, especially for adult patients, for whom compliance has been an issue, along with the fear of emergence of resistant bacterial strains. However, with the available imperfect data, most would suggest prophylaxis in children until 5 years of age or 2 years after splenectomy with penicillin V potassium, 125 mg twice daily. Other antibiotics are also used, including co-amoxiclav, cefotaxime, ceftriaxone, and ciprofloxacin. In adults, with the fact that pneumonia is the only infectious disease ranking in the 10 most common causes of death in the United States, it would require large numbers to be

recorded after splenectomy before it would be possible to say that these were not chance events. Some authors feel that so few reports in the literature can only be interpreted as indicating that infection in adults undergoing splenectomy for benign disease is uncommon, and they are reluctant to agree that this number of reports constitutes a proven increased susceptibility to infection after splenectomy in adults. These authors point to the fact that 73% of the pneumococcal infections reported after splenectomy were made up of isolated case reports.⁴⁵

Despite the controversies, the risk of OPSI should be reduced by the measures already described even if accurate data from any of these interventions are scant. Yet in a study at The Hospital for Sick Children in Toronto, children who had splenectomy between 1958 and 1970 (6% infection, 3.9% mortality) were compared with children who had splenectomy between 1971 and 1975. In the latter group, all the children received prophylactic antibiotics and more than two thirds of them were given polyvalent pneumococcal vaccine. In the latter group, the infection rate was reduced by 47% and the mortality by 88%. The use of vaccines against encapsulated organism is thought to have led to a drop in the overall incidence of OPSI to less than 1%.^{44,47}

OUTCOME EVALUATION

No randomized, prospective trials comparing open splenectomy with laparoscopic splenectomy have yet been conducted. At present, such trials are unlikely to be held, for a variety of reasons. For one thing, randomization is difficult with procedures that are still in evolution. At one end of the spectrum, laparoscopic splenectomy is done for patients with ITP, who usually are relatively healthy and have normal-size spleens. In many of these patients, needlescopic instruments (< 3 mm) can be used in conjunction with a single 12 mm port site in the umbilicus. This approach permits hospital discharge within 24 hours of operation in a significant number of cases. At the other end of the spectrum, laparoscopic splenectomy is done for patients with myeloid metaplasia and spleens longer than 30 cm. In this setting, a laparoscopic approach poses formidable challenges, and the optimal technique and its justification remain to be determined. The window of opportunity for randomized comparative trials may have been lost.

Large case series and nonrandomized comparative trials, however, have consistently reported better outcomes from laparoscopic splenectomy than from open splenectomy (E.C. Poulin, C.M. Schlachta, J. Mamazza, unpublished data, February 2001).^{48–53} For example, in one set of 528 patients [see Table 2],^{49–51} the rate of postoperative pneumonia was 1.1% (6 of 528), and no subphrenic abscesses occurred as postoperative complications (E.C. Poulin, C.M. Schlachta, J. Mamazza, unpublished data, February 2001). Many surgeons who have completed the learning curve associated with the procedure feel that there is still room for improvement regarding complication rates and length of stay for patients with ITP and other relatively benign conditions necessitating laparoscopic splenectomy. The more serious conditions and the mortality seen in conjunction with the procedure tend to occur in patients with advanced hematologic malignancies or megaspleens. In such cases, most of the adverse results are related to the disease state rather than to the operation, and

it remains to be seen whether laparoscopic splenectomy will have a positive effect on outcome.

One of the great attractions of minimally invasive surgery has been the prospect of significant cost reductions. At this point in the development of laparoscopic splenectomy, however, we are reluctant to place too much trust in premature cost analyses that do not take into account the “work in progress” nature of minimally invasive surgery. Most surgeons can now perform most laparoscopic splenectomies with simplified trays of reusable instruments. Our basic laparoscopic tray contains a few instruments and two sizes of reusable clip appliers with inexpensive clips. As noted [see Operative Technique, *above*], clips are used for distributed-type spleens, and single-use linear staplers are mostly used for magistral-bundled type spleens. To reduce costs, ultrasonic dissectors are rarely used. In addition, the use of commercially available freezer bags instead of laparoscopic retrieval bags further reduces the cost of specimen extraction. Finally, even if intraoperative costs are higher with laparoscopic splenectomy, our experience is that the increase is offset by reductions in postoperative stay.¹⁹

We, like most authorities, believe that as a surgeon gains experience with laparoscopic splenectomy, operating time tends to fall until it approaches that of open splenectomy. We also concur with the numerous authors who have suggested that once laparoscopic splenectomy is mastered, use of blood products tends to decrease substantially.

Open Splenectomy

PREOPERATIVE EVALUATION

With the growing acceptance of laparoscopic splenectomy, the indications for open splenectomy have essentially been reduced to (1) elective removal of megaspleens and (2) treatment of splenic trauma when conservative treatment either is not indicated or has failed. In rare cases, open splenectomy may be done for iatrogenic injuries incurred during left upper quadrant surgical procedures.

Preoperative evaluation for elective open splenectomy is similar to that for laparoscopic splenectomy [see Laparoscopic Splenectomy, Preoperative Evaluation, *above*]. Preoperative evaluation of trauma patients is covered in more detail elsewhere. Essentially, a coagulogram and blood typing and cross-matching are required. A preoperative CT scan will have established the size of the spleen, the grade of the splenic injury, the presence of other injuries (if any), and, in elective cases, the location and configuration of any masses or cysts.

OPERATIVE PLANNING

Most surgeons would agree that the lessons learned from successful performance of minimally invasive procedures have had a positive impact on the refinement of the corresponding open procedures. The principles of careful appreciation of fine anatomic details (as described for laparoscopic splenectomy) and maximal reduction of tissue trauma from retractors or excessive tissue handling should be incorporated into the planning of open splenectomy.

Total versus Partial Splenectomy

As a consequence of the recognition that splenectomy renders patients susceptible to a lifelong risk of OPSI, it is now

*71% required accessory incision because of spleen size.

routine practice to attempt splenic conservation. Accordingly, saving normally functioning splenic parenchyma has become the most important goal in the management of splenic injuries. In some 50% of adults (and over 80% of children), this goal can be achieved by means of nonoperative treatment. In approximately 20% of adults, splenorrhaphy and partial splenectomy are possible; splenectomy is indicated in the remainder. Partial splenectomy is also favored on occasion when excision of splenic tissue is required for the treatment of other elective conditions.³¹

For the sake of brevity, we describe the surgical technique for total splenectomy and partial splenectomy concurrently, noting differences only where significant.

OPERATIVE TECHNIQUE

Step 1: Incision

The patient is supine, in a reverse Trendelenburg position with a 15° tilt to the right. For maximal exposure, a midline incision is made, starting on the left side of the xiphoid process [see Figure 17]. The incision is extended below the umbilicus for a variable distance, depending on circumstances such as the size of the patient, the surgical situation (traumatic versus nontraumatic), the possibility of associated injury, and the size of the spleen. Occasionally, a left subcostal incision may be used for nontraumatic indications in patients with normal-size spleens. This incision may be extended onto the right side to form a chevron incision if necessary; however, this may impede the search for accessory spleens. Some surgeons have performed splenectomy via a thoracoabdominal approach, but most have abandoned this approach. Appropriate retraction of the left lobe of the liver and the abdominal wall is achieved with the help of surgical assistants placed on each side of the table or the use of self-retaining retractors.

Troubleshooting In trauma cases, the anesthetist should always be informed when the peritoneum is opened; release

Figure 17 Open splenectomy. Shown are midline and left subcostal incisions.

of a tense hemoperitoneum can precipitate hypotension with the loss of tamponade.

Step 2: Evacuation of Blood and Packing of the Abdomen

In trauma cases, gross blood and clots are evacuated manually with large laparotomy sponges. All quadrants of the abdomen are then packed with laparotomy pads. Standard suction equipment is not very useful for evacuating large quantities of blood from the abdomen.

Step 3: Control of Splenic Artery

Once other major injuries are excluded, the first decision to be made is whether to control the splenic artery first or to

mobilize the spleen to the midline. This decision is dictated by the urgency of the clinical situation, the spleen size, and the presence of underlying disease.

If the decision is made to control the splenic artery first, the main splenic trunk is identified above the pancreas via an approach that leads to the lesser sac either through the gastrocolic ligament or through the avascular plane of the greater omentum above the distal transverse colon. Once dissected, the artery is controlled with a vascular loop. The main artery can also be accessed and dissected posteriorly after the spleen is mobilized [see Figure 18].

Troubleshooting One advantage of dissecting the splenic artery in the lesser sac (as opposed to the hilum) is that the splenic vein is rarely damaged, being located under the pancreas and away from the artery. Good proximal control of the splenic blood supply facilitates the performance of the more complex variations of partial splenectomy or total splenectomy for megaspleens.

Step 4: Mobilization of Spleen

If the decision is made to mobilize the spleen first, as in most trauma cases, mobilization should be carried out in a carefully planned manner; it is all too easy to compound splenic injury with ill-advised maneuvers that obligate the surgeon to perform a total splenectomy.

Gastric decompression is ensured with a properly placed nasogastric tube. The spleen is then retracted anteromedially with the left hand, with care taken to confirm proper retraction of the left abdominal wall. The phrenicocolic ligament is thereby placed on stretch, and the ligament insertion on the lateral abdominal wall serves as countertraction. The phrenicocolic ligament is then incised from the bottom up with either long scissors or the 45°-angle tip of a monopolar cautery [see Figure 19]. Efforts should be made to leave 2 cm of ligament on the spleen side and to avoid capsular injury. If the surgeon cannot put a finger behind the ligament, an

Figure 18 Open splenectomy. The splenic artery is controlled above the pancreas in the lesser sac. The artery must be ligated distal to the pancreatic magna artery.

Figure 19 Open splenectomy. With the spleen retracted medially, the phrenicocolic ligament is incised.

assistant should elevate the ligament between the jaws of a right-angle clamp. The incision of the phrenicocolic ligament is then extended to the left crus of the diaphragm. Except in patients with portal hypertension or myeloproliferative disorders, this ligament is avascular. The left lateral portion of the gastrocolic ligament (the greater omentum) is also dissected away from the splenic flexure of the colon to facilitate mobilization of the spleen. At this point, the splenocolic ligament and the sustentaculum lienis are left alone.

After complete division of the phrenicocolic ligament, a plane is developed between the pancreas and the retroperitoneal structures with gentle blunt finger dissection. The spleen can then be delivered to the midline, where the splenectomy can be planned in an unhurried manner [see Figure 20]. Continuing splenic bleeding during this maneuver can be controlled with manual compression of the organ. The splenic pedicle may also be gently compressed between the thumb and the index finger at this stage. Laparotomy sponges are placed in the left subphrenic space.

Troubleshooting When performing elective resections of very large spleens, experienced spleen surgeons use a few tricks to simplify the procedure. In most patients with megaspleens, the suspensory ligaments have been stretched over time, allowing the surgeon much more leeway in mobilizing or turning the spleen. This greater leeway allows the surgeon to rotate the spleen from the lower pole so as to deliver it transversely into the incision. Thus, the presence of a large spleen does not always necessitate the creation of a long xiphopubic incision, because a transversely placed spleen can be extracted into the abdominal wall through a shorter incision.

Step 5a (Total Splenectomy): Planning of Resection

To devise the appropriate operative strategy, the surgeon performing open total splenectomy must address the same

Figure 20 Open splenectomy. The spleen is delivered to the midline by means of blunt and sharp dissection of the areolar plane between the kidney and the pancreas.

anatomic issues that he or she would if performing laparoscopic total splenectomy—for example, the nature of the splenic blood supply (distributed or bundled) and the distance between the tip of the pancreas and the splenic hilum. The anatomy must be appreciated before the operative strategy can be defined.

Once the spleen has been delivered into the abdominal wall, various techniques may be employed to control the blood supply. The classic approach is to serially clamp, ligate, or suture-ligate the vessels between curved clamps, starting from the lower pole. Alternatively, the vessels may be controlled with clips.

Troubleshooting We frequently use laparoscopic clip appliers to achieve vascular control in open splenectomy. The long, slender design of these devices is particularly useful in obese patients, in whom it is often difficult to achieve complete mobilization of the spleen without causing additional splenic trauma. With laparoscopic clip appliers, vessels can be safely controlled inside the abdomen. Locking plastic clips may also be used. Moreover, provided that the same precautions are taken as in laparoscopic splenectomy, a linear stapler with a vascular cartridge may be used to control the hilum in one step once the gastroepiploic branches have been controlled.

Step 5b (Partial Splenectomy): Planning of Resection

Once the spleen is appropriately placed for full evaluation and adequate hemostasis is ensured, planning for partial splenectomy can start. In trauma cases, such planning is guided by the extent of the injury, and in elective cases, it is guided by the nature of the underlying pathologic condition [see Table 3].

Table 3 Indications and Contraindications for Partial Splenectomy

Indications
Selected grade II–IV splenic injuries with the following:
Hemodynamic stability
No evidence of other intra-abdominal organ injury
No associated head injury
No coagulopathy
CT confirmation of isolated splenic injury
Selective elective indications
Resection of nonparasitic cysts
Hamartomas and other benign splenic tumors
Inflammatory pseudotumor of the spleen
Type I Gaucher disease
Cholesteryl ester storage disease
Chronic myelogenous leukemia
Thalassemia major
Spherocytosis
Staging of Hodgkin disease in children
Absolute/relative contraindications in trauma
Inadequate exposure
Inability to mobilize spleen and tail of pancreas to midline
Inability to leave > 25% of splenic mass for complete splenic function

CT = computed tomography.

In most cases, as noted, the spleen can be divided into independent lobes or segments, each with its own terminal blood supply. The superior pole is supplied by the short gastric vessels, and the lower pole is supplied by branches of the gastroepiploic artery, which are known to form anastomoses with the inferior polar artery. In addition, most patients, possible variations notwithstanding, have two or three major vessels entering the hilum. Thus, usually four or five discrete regions or lobes may be removed, individually or in combination, in a partial splenectomy. It should be kept in mind that the vessels supplying the spleen lie in different supportive ligaments. The vessels supplying the superior pole (the short gastrics) and the inferior pole (the gastroepiploic branches) rest in the gastrosplenic ligament, whereas the splenic branches proper lie in the splenorenal ligament along with the tail of the pancreas.

Step 6 (Partial Splenectomy): Exposure of Entire Hilum and Ligation of Appropriate Arteries

The entire hilum of the spleen is then exposed close to the parenchyma. The gastrosplenic ligament and the splenorenal ligament must be separated, with care taken to preserve the blood supply to both poles of the spleen. There is a fairly avascular area of the gastrosplenic ligament, between the short gastric vessels supplying the superior pole and the gastroepiploic branches supplying the lower pole, that must be opened; once this is done, a complete view of the entire splenic blood supply is available. The surgeon can then determine whether partial splenectomy is feasible and how many lobes he or she can resect while still leaving enough spleen tissue behind for adequate splenic function. Any number of segmental resections are possible. If the surgeon is unsure of the extent of the necessary resection, an accurate assessment can be made by temporarily compressing the splenic arterial branches.

Selected arterial branches are then carefully dissected as close to the spleen parenchyma as possible, with the understanding that the veins are situated posteriorly in close

proximity. The vessels may be doubly ligated, transfixed, or clipped. If clips are used, care is taken not to dislodge them with inappropriate manipulations. Once the arterial blood supply is controlled, the affected area of the spleen will rapidly become visibly demarcated. If the devitalized area of the spleen corresponds to the intended resection, a similar technique is applied to the venous side. Access to the venous side can also be achieved from the posterior aspect of the spleen. When this approach is followed, it is helpful to identify the tail of the pancreas if possible to avoid inadvertent damage: the tail of the pancreas touches the hilum of the spleen in 30% of cases and lies within 1 cm of the hilum in 70%.

Step 7 (Partial Splenectomy): Incision of Splenic Capsule and Partial Resection of Spleen

The capsule of the spleen is incised circumferentially with a scalpel or a monopolar cautery, and a 5 mm rim of devitalized tissue is left in situ. The splenic fragments may be transected with a scalpel, scissors, a monopolar cautery, or a combination thereof. Various techniques have been used to control residual bleeding, including use of a monopolar cautery on spray current; use of a cutaneous ultrasonic surgical aspirator; use of an argon beam coagulator; suture compression, with or without Teflon pledgets; and omental pedicle packing. One low-tech way of dealing with residual hemostatic requirements is to employ the hollow part of a Poole suction device to aspirate blood while employing a coagulating monopolar current on the suction tip. In some cases, wrapping the splenic remnant in an absorbable polyglycolic mesh is useful. Our experience suggests that when enough residual devitalized tissue (i.e., at least 5 mm) is left behind circumferentially, good hemostasis is easily achieved,

typically requiring nothing more than simple measures and topical agents. No drains are used unless the tail of the pancreas has been damaged, in which case a closed-suction drain is placed.

POSTOPERATIVE CARE

The principles of postoperative care are essentially the same for open splenectomy as for laparoscopic splenectomy [see Laparoscopic Splenectomy, Postoperative Care, *above*], although most authors agree that the pace of aftercare is slower with the former. It should be kept in mind that acute postoperative gastric distention occurs more frequently in children and may necessitate more prolonged gastric decompression.

COMPLICATIONS

The complications seen after open splenectomy are the same as those seen after its laparoscopic counterpart [see Laparoscopic Splenectomy, Complications, *above*]. Hemorrhagic complications may necessitate transfusion, reoperation, or both.

Although the rate of serious postoperative infection after splenic surgery is generally considered to be 8%, it is thought to be lower in patients undergoing splenorrhaphy or partial splenectomy. The lower rate is probably attributable to the presence of less severe underlying injuries rather than to the preservation of splenic tissue. Infectious complications usually manifest themselves between postoperative days 5 and 10 and are typically diagnosed by means of physical examination, chest x-ray, ultrasonography, and CT.

Financial Disclosures: The General Surgery Division at the Ottawa hospital has unrestricted grants from Storz and Covidien. The General Surgery Division at the University of Western Ontario has an unrestricted grant from Johnson and Johnson.

26 ADRENALECTOMY

Steven Hodgett, MD, and L. Michael Brunt, MD

The surgical approach to the adrenals has evolved substantially over the past decade with the development and refinement of techniques for performing laparoscopic adrenalectomy. At present, the majority of adrenal tumors are removed laparoscopically because minimally invasive approaches result in reduced pain, faster recovery, and fewer complications and because the rate of adrenal malignancy is low. Nevertheless, open adrenalectomy still has a role in the management of selected patients with large or malignant tumors. With both open adrenalectomy and laparoscopic adrenalectomy, several different surgical approaches to the adrenals are possible [see *Operative Planning, Choice of Procedure, below*]. Regardless of the particular approach followed, the keys to successful adrenalectomy are the same: proper patient selection for operation, a solid understanding of adrenal pathophysiology, and a thorough knowledge of adrenal anatomy.

Anatomic Considerations

The adrenal glands are retroperitoneal organs that lie along the superomedial aspects of the two kidneys [see *Figure 1*]. Each gland comprises two discrete anatomic and functional units: the adrenal cortex, which is the site for synthesis and secretion of cortisol, aldosterone, and adrenal androgens, and the medulla, which is derived from the neural crest and is the site for synthesis of the catecholamines epinephrine and norepinephrine. A normal adrenal gland typically weighs between 4 and 6 g and measures approximately 4 to 5 cm by 2 to 3 cm by 0.5 to 1 cm. The right adrenal is relatively pyramidal in shape, whereas the left is somewhat flattened and is more closely applied to the kidney. Grossly, the adrenals may be distinguished from the surrounding retroperitoneal fat by their golden-orange color, which is a result of the high intracellular lipid content. The glands have a fibrous capsule but

Figure 1 Depicted is the relation of the adrenal glands to adjacent structures.

are relatively fragile and can be easily cracked or fragmented with surgical manipulation.

RIGHT ADRENAL

Anteriorly, the right adrenal is partially covered by the liver and the right triangular ligament. The gland abuts the inferior vena cava (IVC) medially and may, in part, lie posterior to the lateral aspect of the vena cava. Inferiorly, the adrenal sits just above the upper pole of the kidney. The diaphragm forms the posterior and lateral boundaries of the gland.

The blood supply of the right adrenal is derived from branches of the inferior phrenic artery, the right renal artery, and the aorta [see Figure 2]. Typically, multiple small branches enter the gland along its superior, medial, and inferior aspects. Arterial branches from the aorta generally course posterior to the vena cava before entering the adrenal. Each adrenal is drained by a single central vein. On the right, this vein is short (1 to 1.5 cm long), runs transversely, and joins the lateral aspect of the IVC. In some cases, a more superiorly located accessory adrenal vein may enter either the IVC or one of the hepatic veins. Control of the adrenal vein is the most critical aspect of right adrenalectomy in that the short course of this vessel makes it susceptible to tearing or avulsion from the IVC.

LEFT ADRENAL

The spleen and tail of the pancreas overlie the anterior and medial borders of the left adrenal. The inferolateral aspect of the gland lies over the superomedial aspect of the left kidney, to which it is more closely applied than the right adrenal is to the right kidney. The inferior aspect of the adrenal is in close proximity to the renal vessels, especially the renal vein. As on the right side, the posterior aspect of the adrenal rests on the diaphragm.

The arterial blood supply of the left adrenal is similar to that of the right adrenal [see Figure 2]. The left adrenal vein is longer than the right adrenal vein and runs somewhat obliquely from the inferomedial aspect of the gland to enter the left renal vein. The inferior phrenic vein courses in a superior-to-inferior direction just medial to the adrenal and usually joins the left adrenal vein cephalad to its junction with the renal vein.

Preoperative Evaluation

INDICATIONS FOR OPERATION

The main indications for adrenalectomy are well established [see Table 1]. Any adrenal lesion that either is hypersecretory for one of the adrenal hormones or appears to be malignant or

Figure 2 Depicted is the adrenal blood supply. Multiple adrenal arteries are present; a single central adrenal vein drains into the inferior vena cava on the right side and the renal vein on the left side.

Table 1 Indications for Adrenalectomy

Aldosteronoma
Cushing syndrome
Cortisol-producing adenoma
Primary adrenal hyperplasia
Failed treatment of ACTH-dependent Cushing syndrome
Pheochromocytoma
Sporadic or familial
Malignant pheochromocytoma
Nonfunctioning incidental lesion
≥ 4–5 cm or atypical radiologic appearance
Adrenal metastasis
Solitary, unilateral in the absence of extra-adrenal cancer
Adrenal cortical carcinoma
Adrenal sarcoma
Adrenal myelolipomas (only if symptomatic or enlarging)
Miscellaneous other lesions (atypical cysts, ganglioneuromas)

ACTH = adrenocorticotrophic hormone.

possibly malignant should be removed. In selected cases, it may be appropriate to remove adrenal metastases if they are solitary and if there is no evidence of extra-adrenal metastatic disease. Nonfunctioning adrenal lesions that appear to be benign on the basis of their size (< 4 cm) and their appearance on computed tomography (CT) or magnetic resonance imaging (MRI) need not be removed unless they enlarge during follow-up. Adrenal myelolipomas and cysts usually can be diagnosed radiographically and should not be removed unless they cause symptoms or if there is uncertainty in the diagnosis.

Most of the conditions for which adrenalectomy is indicated are amenable to a laparoscopic approach. However, the role of laparoscopy in patients with large adrenal tumors (> 6 to 8 cm) or potentially malignant primary adrenal lesions remains controversial. In the presence of a locally invasive tumor, a laparoscopic approach is contraindicated because of the need to perform en bloc resection of the tumor and any adjacent involved structures.

COMMON ADRENAL TUMORS

A brief review of the pertinent clinical and biochemical features of the various hypersecretory adrenal tumors [see Table 2] will facilitate evaluation of adrenal lesions (including adrenal incidentalomas) and planning for adrenal surgery.

Table 2 Clinical and Diagnostic Features of Common Adrenal Tumors

Adrenal Tumor	Clinical Presentation	Biochemical Testing	Preferred Method of Imaging/Localization
Aldosteronoma	Hypertension ± hypokalemia	Elevated PAC with suppressed PRA (PAC:PRA > 20–30)	Thin-section (3 mm) adrenal CT
		Urine aldosterone > 12 µg/24 hr	Adrenal vein sampling
		Urine potassium > 30 mEq/24 hr	
Cortisol-producing adenoma (Cushing syndrome)	Centripetal obesity, moon facies, hypertension, purple skin striae, osteopenia, plethora, amenorrhea	Elevated 24 hr urinary free cortisol	Abdominal CT
		Nonsuppressed low-dose dexamethasone test	
		Decreased plasma ACTH	
Pheochromocytoma	Severe episodic hypertension or hypertension with spells of tachycardia, headache, anxiety, and diaphoresis	Elevated plasma fractionated metanephrines or urinary catecholamines and metabolites	MRI (T ₂ -weighted sequences showing bright-appearing adrenal lesion)
			¹²³ I-MIBG scan or Octreo-scan if MRI is negative or if malignant or extra-adrenal tumor is suspected
Adrenal cortical carcinoma	Cushing syndrome, virilizing features, local pain or mass	24 hr urinary free cortisol and metabolites	CT of chest/abdomen/pelvis
		Plasma DHEA-sulfate	
Adrenal metastasis	None (often seen on follow-up imaging) or local pain	Plasma fractionated metanephrines and low-dose DM test to exclude functioning lesion	Abdominal CT, PET imaging to evaluate for extra-adrenal metastatic disease
		FNA biopsy only if unresectable	
Myelolipoma	None; occasionally local pain	None if radiographic appearance is unequivocal for myelolipoma	Presence of macroscopic fat on CT or MRI

ACTH = adrenocorticotrophic hormone; CT = computed tomography; DHEA = dehydroepiandrosterone; DM = dexamethasone; FNA = fine-needle aspiration; MIBG = metaiodobenzylguanidine; MRI = magnetic resonance imaging; PAC = plasma aldosterone concentration; PET = positron emission tomography; PRA = plasma renin activity.

Aldosteronoma

Primary hyperaldosteronism is the most common form of secondary hypertension, and aldosterone-producing adenoma is the most common hypersecretory adrenal tumor. The prevalence of this diagnosis is much higher than was previously thought,^{1,2} reaching levels as high as 12% of hypertensive individuals in some series.¹ The classic finding in primary hyperaldosteronism is hypertension in conjunction with hypokalemia, but many patients have a normal or low-normal serum potassium level. The hypertension in these patients is often refractory to standard medical therapy. Therefore, any patient who becomes hypertensive at an early age or who has malignant or difficult-to-control hypertension should be screened for this diagnosis. Screening consists of measuring plasma aldosterone concentration (PAC) and plasma renin activity (PRA). A PAC-to-PRA ratio higher than 25 to 30, in conjunction with a plasma aldosterone concentration higher than 15 ng/dL and renin < 0.5 ng/mL/hr, is suggestive of the diagnosis and should be confirmed by suppression measuring 24-hour urine aldosterone, sodium, and potassium levels while the patient is on a high-sodium diet.² A 24-hour urine aldosterone level higher than 12 µg/24 hr in this setting is confirmatory; the urine potassium should be > 30 mEq/24 hr.

Because 25% or more of cases of primary hyperaldosteronism may be idiopathic as a result of bilateral adrenal hyperplasia and should therefore be managed medically and not surgically, the next step should be imaging with thin-section (3 mm cuts) CT or MRI. The finding of a discrete unilateral adenoma larger than 1 cm on CT in conjunction with a normal contralateral adrenal is sufficient localization to allow the surgeon to proceed with adrenalectomy. If CT shows bilateral nodules, bilateral normal adrenals, or a unilateral nodule smaller than 1 cm, then adrenal vein sampling for aldosterone and cortisol should be done to determine whether a unilateral gradient of increased aldosterone production exists.³

Cortisol-Producing Adenoma

Approximately 20% of cases of Cushing syndrome are related to increased production of cortisol by an adrenal cortical tumor. Adrenal Cushing syndrome is most commonly attributable to adenoma but may also result from adrenal cortical carcinoma or primary adrenal hyperplasia. The classic features of full-blown Cushing syndrome are usually obvious and include centripetal obesity, moon facies, hypertension, purple skin striae, proximal muscle weakness, osteopenia, and amenorrhea. Not all patients present with advanced clinical signs, however, and the high prevalence of hypertension and obesity in the general population necessitates liberal use of diagnostic testing.

Suspected Cushing syndrome should be evaluated initially by measuring 24-hour urinary free cortisol levels or by administering a single low-dose dexamethasone test. Plasma cortisol that does not fall to a level below 3 to 5 µg/dL the morning after administration of 1 mg of dexamethasone at 11 pm is indicative of a loss of autonomy of cortisol secretion, and further testing is required. Once the diagnosis of hypercortisolism is established, plasma levels of adrenocorticotropic hormone (ACTH) should be measured to differentiate ACTH-dependent (resulting from increased ACTH production by a pituitary tumor or an ectopic source) from

ACTH-independent (primary adrenal) causative conditions. The plasma ACTH level should be in the low-normal or suppressed range in patients with primary adrenal tumors, whereas it is normal or elevated in patients with ACTH-dependent Cushing syndrome. Imaging should then be carried out with CT (or MRI) to localize the adrenal tumor.

Pheochromocytoma

Pheochromocytoma should be suspected in any patient who experiences either severe episodic hypertension or hypertension that is associated with spells of tachycardia, headache, anxiety, and diaphoresis. Biochemical evaluation consists of measuring urinary concentrations of catecholamines and metabolites (e.g., metanephrine and normetanephrine), plasma concentrations of fractionated metanephrines, or both. MRI is our preferred imaging modality for suspected pheochromocytomas because of the typical bright appearance these tumors exhibit on T₂-weighted imaging sequences. Occasionally, radionuclide imaging with iodine-123–metaiodobenzylguanidine (¹²³I-MIBG) or octreotide scintigraphy is necessary to localize an extra-adrenal pheochromocytoma.

Adrenocortical Carcinoma

Adrenocortical carcinomas are rare, with an incidence of approximately one per 1.5 to 2.0 million in the general population. These tumors are typically large (> 6 to 8 cm) at diagnosis, and most patients have advanced (stage III or IV) disease at presentation. Consequently, patients often have a mass or complain of abdominal or back pain. A significant percentage of patients with adrenocortical carcinoma present with evidence of hormone overproduction in the form of Cushing syndrome or virilizing features. Complete surgical resection offers the only chance for cure; thus, the role of laparoscopic adrenalectomy in the treatment of adrenocortical carcinoma remains controversial [see Troubleshooting, Large Tumors, *below*].

Adrenal Incidentaloma

Adrenal incidentalomas are the adrenal lesions most frequently referred to surgeons and are seen on 1 to 5% of all abdominal CT scans.⁴ Practical recommendations for the evaluation and management of patients with incidentally discovered adrenal lesions are available.^{5,6} The most common adrenal incidentaloma is a nonfunctioning cortical adenoma for which adrenalectomy is not usually required. All patients with adrenal incidentalomas should be screened for hypercortisolism by administering an overnight low-dose dexamethasone test and for pheochromocytoma by measuring plasma concentrations of fractionated metanephrines or urine levels of catecholamines and metanephrines. Patients who are hypertensive or hypokalemic should also undergo testing for hyperaldosteronism with measurement of plasma aldosterone and renin levels. Some patients with adrenal incidentalomas are found to have subclinical Cushing syndrome with evidence of autonomous corticoid steroid production, as demonstrated by lack of suppressibility with a dexamethasone test and by low plasma ACTH levels.⁷ These patients do not exhibit the classic features of Cushing syndrome but do have a high incidence of hypertension, diabetes, and osteoporosis. Adrenalectomy is generally indicated if the operative risk is suitably low. Supplemental corticosteroids should be given before, during, and

after operation because contralateral adrenal function is often suppressed and adrenal insufficiency may ensue.

The nonfunctioning adrenal lesion should also be assessed for malignant potential on the basis of its size and appearance on diagnostic imaging. Cortical adenomas typically have low attenuation values (< 10 Hounsfield units) on unenhanced CT imaging and show loss of signal intensity on MRI chemical shift imaging sequences. Needle biopsy is not useful in differentiating benign from malignant primary adrenal lesions and is rarely indicated. Adrenal biopsy should never be done unless a pheochromocytoma has first been excluded biochemically. Most experts recommend removing any nonfunctioning adrenal lesion larger than 4 to 5 cm unless the radiographic appearance of the lesion is diagnostic of a cyst or myelolipoma. Smaller tumors should be followed with imaging at 4 and 12 months after the initial presentation.

Operative Planning

PREPARATION FOR OPERATION

Preoperative preparation of the patient for adrenalectomy entails control of hypertension and correction of any electrolyte imbalances. Patients with a pheochromocytoma should receive 7 to 10 days of alpha-adrenergic blockade with phenoxybenzamine to minimize any exacerbation of hypertension during the operation. The usual starting dosage is 10 mg twice daily, which is increased by 10 to 20 mg/day until the hypertension and tachycardia are controlled and the patient is mildly orthostatic. Patients with Cushing syndrome or subclinical Cushing syndrome should receive perioperative dosages of stress steroids. Mechanical bowel preparation is not routinely employed.

CHOICE OF PROCEDURE

The retroperitoneal location of the adrenals renders them accessible via either transabdominal or retroperitoneal approaches. The choice of surgical approach in any given patient depends on a number of factors, including the nature of the underlying adrenal pathology, the size of the tumor, the patient's body habitus, and the experience of the operating surgeon. For the vast majority of adrenal lesions, laparoscopic adrenalectomy is preferred. Most centers favor the transabdominal lateral approach to laparoscopic adrenalectomy,⁸ which has the advantages of a large working space, familiar anatomic landmarks, and widespread success. Some centers, however, prefer a retroperitoneal endoscopic approach.^{9,10} The advantages of this technique are that the peritoneal cavity is not entered, there is no need to retract overlying organs, and the incidence of postoperative ileus may be lower. The disadvantages are that the retroperitoneal approach employs a smaller working space, is more difficult to learn with fewer anatomic landmarks for orientation, and may be more difficult with larger tumors.

The only absolute contraindications to laparoscopic adrenalectomy are local tumor invasion and the presence of regional lymphadenopathy. Cases in which the adrenal tumor is large (> 8 to 10 cm), are suspected to be primary adrenal malignancies; a history of previous nephrectomy, splenectomy, or liver resection on the side of the lesion to be removed should be considered relative contraindications to a laparoscopic approach in all but the most experienced hands. Portal

hypertension is also a contraindication to a laparoscopic approach because of the dilated collateral vessels in the retroperitoneum.

Options for open adrenalectomy include transabdominal, flank, posterior retroperitoneal, and thoracoabdominal approaches. The lateral flank approach and the posterior retroperitoneal approach have been replaced by laparoscopic approaches and are now rarely used. Open posterior retroperitoneal adrenalectomy is done through a hockey-stick incision in the back, with subperiosteal resection of the 12th rib. This approach has low morbidity and yields adequate exposure of the adrenal gland, but the visual field is often limited, and there is a high incidence of residual incisional complaints. The current consensus is that open posterior retroperitoneal adrenalectomy is indicated only in patients who require bilateral adrenalectomy but are not candidates for laparoscopic adrenalectomy. Most large or malignant adrenal tumors that necessitate an open approach can be removed via an anterior abdominal incision, usually a unilateral or bilateral subcostal incision (with subxiphoid extension if necessary); a thoracoabdominal incision is rarely needed.

Operative Technique

LAPAROSCOPIC ADRENALECTOMY

Transabdominal Approach

Patient positioning A gel-padded bean-bag mattress is placed on the operating table before the patient enters the room. The patient is placed in the supine position, general anesthesia is induced, and sequential compression stockings are placed. A urinary catheter may be optional for uncomplicated cases but should be used for all pheochromocytomas and larger tumors. The stomach may be decompressed with an orogastric tube. Invasive monitoring is not usually necessary unless the patient has a vasoactive pheochromocytoma, in which case, an arterial line is routinely placed.

Next, the patient is moved into a lateral decubitus position with the affected side up [see Figure 3]. A soft roll is placed

Figure 3 The patient is placed in a lateral decubitus position with the affected side up (here, right lateral decubitus for left adrenalectomy).

underneath the chest wall to protect the axilla. The bean-bag mattress is molded around the patient and the legs are wrapped in a foam pad to protect all pressure points. The patient is secured to the operating table with tape placed across the padded lower extremities and a safety strap across the pelvis. The operating table is then flexed at the waist. The combination of the lateral position, the flexed operating table, and the reverse Trendelenburg position facilitates placement of the laparoscopic ports and provides optimal access to the superior retroperitoneum.

Equipment Our preferred instrumentation for laparoscopic adrenalectomy is as follows [see Table 3]. An angled (30°) laparoscope, preferably 5 mm in diameter, is used to optimize viewing angles. One 10/12 mm port is employed to allow insertion of a clip applier and extraction of the specimen; the other ports can all be 5 mm if a 5 mm laparoscope is employed. The principal instruments needed for dissection and hemostasis are atraumatic graspers, an L-hook electrocautery, and a medium-large clip applier. An ultrasonic coagulator or bipolar coagulation device is optional for right adrenalectomy, but both are very useful for mobilization of the splenic ligaments and dissection of the adrenal from the retroperitoneal fat during a left adrenalectomy. An endovascular stapler should be available for a right adrenalectomy because it will occasionally be needed to divide the right adrenal vein. Other essential items are a suction-irrigation device and an impermeable specimen retrieval bag.

Initial access and placement of trocars Because the patient is in a lateral position, initial access to the peritoneal cavity is usually achieved in a closed fashion with a Veress needle. After insufflation to a pressure of 15 mm Hg, a 5 mm direct-view trocar is placed to afford direct visualization of the peritoneal cavity. An open insertion technique may be used instead, but this approach requires a larger incision and is hindered somewhat by the bulky overlapping muscle layers in the subcostal region. Open insertion at the umbilicus is an option in nonobese patients.

The initial access site is generally at or somewhat medial to the anterior axillary line about two fingerbreadths below the

costal margin [see Figure 4]. Subsequent ports should be placed at least 5 cm apart to allow freedom of movement externally. The most dorsal port should be approximately at the posterior axillary line. It is helpful to outline the anterior and posterior axillary lines with a marker before the patient is prepared to ensure that the ports are positioned properly. Four ports are required for a right adrenalectomy, but a left adrenalectomy can be done with either three or four ports, depending on the surgeon's preference and experience. On the left side, the splenic flexure of the colon usually must be mobilized before the fourth port (the most dorsal one) can be inserted.

Right adrenalectomy *Step 1: exposure of right adrenal gland and vein* The key to exposure of the right adrenal gland is extensive division of the right triangular ligament of the liver. This maneuver should be continued until the liver can be easily elevated and retracted medially and both the right adrenal and the IVC are visible. A retractor is then inserted through the most medial port to hold the right lobe of the liver up and away from the operative site [see Figure 5].

Next, the plane between the medial border of the adrenal and the lateral aspect of the IVC is developed. An L-hook cautery is used for gentle elevation and division of the peritoneum and the small arterial branches here [see Figure 5]. The adrenal is pushed laterally with an atraumatic grasper to apply traction to the dissection site; however, the gland itself should not be grasped because it is fragile, and the capsule and adrenal parenchyma are easily fractured. At all times, it is imperative to know where the lateral border of the vena cava is, both to ensure that the dissection is extra-adrenal and to avoid injuring it. The right adrenal vein should come into view as the medial border is dissected.

Step 2: isolation, clipping, and division of right adrenal vein The right adrenal vein is first exposed by gentle blunt spreading, and a right-angle dissector is then used to isolate enough of the vein to permit clip placement [see Figure 6]. A medium-large clip is usually sufficient for securing the vein, although sometimes it is necessary to use larger clips or even an endovascular

stapler. (We use an endovascular stapler primarily in cases in which the tumor is located in the medial area of the adrenal and the vein must be taken along with a portion of the IVC

a

junction.) Usually, two clips are placed on the IVC side and one or two on the adrenal side, depending on the length of vein available. Meticulous hemostasis throughout the dissection is important: even minimal bleeding will stain the tissue planes and make the dissection more difficult and potentially treacherous.

Step 3: mobilization and detachment of specimen Once the adrenal vein is divided, dissection is continued superiorly and inferiorly with the L-hook cautery. The numerous small arteries that enter the gland at its superior, medial, and inferior margins can be safely cauterized, but larger branches may have to be clipped. Superiorly, as the adrenal is mobilized, the musculature of the posterior diaphragm is exposed and serves as a marker of the proper plane for the posterior dissection. Inferiorly, the dissection should stay close to the margin of the adrenal so as not to injure vessels to the superior pole of the kidney. The inferior dissection then proceeds in a medial-to-lateral direction as the gland is elevated off the superior pole of the right kidney. The remaining attachments to the back muscles and the retroperitoneal fat are relatively avascular and can be divided with the electrocautery or other coagulation device.

Once the specimen has been detached, it is placed in an impermeable bag. The retroperitoneum is then irrigated and inspected for hemostasis and for secure placement of the clips on the IVC.

Step 4: extraction of specimen The fascial opening at the 10/12 mm port site is enlarged somewhat, and the specimen bag is removed through this site. For larger tumors, a remote extraction site (e.g., the umbilicus or the suprapubic region) may be a preferable alternative. Large pheochromocytomas may be morcellated within the entrapment bag and removed piecemeal, but, ideally, cortical tumors and metastatic lesions should be extracted intact to permit full pathologic examination.

b

Figure 6 Once the right adrenal and adrenal vein are exposed, the vein is isolated and clipped. Shown are (a) a schematic representation and (b) an intraoperative view showing the right adrenal gland/tumor (A), the right adrenal vein (AV), and the inferior vena cava (IVC).

Left adrenalectomy *Step 1: exposure of left adrenal gland and vein* The splenic flexure of the colon is mobilized. The lateral attachments of the flexure are divided to allow placement of the fourth port, and the colon is then released from the inferior pole of the spleen and away from the left kidney. Next, the splenorenal ligament is incised from the inferior pole of the spleen to the diaphragm to allow full medial rotation of the spleen and provide access to the left retroperitoneum [see Figure 7]. It is important not to dissect lateral to the kidney; doing so will cause the kidney to tilt forward and will interfere with exposure. Once the spleen is completely mobilized, it should fall medially, with minimal or no retraction needed to keep it out of the operative field. Division of the ligaments can be accomplished more quickly and with less bleeding if an ultrasonic coagulator is used.

At this point in the dissection, the tail of the pancreas should be visible, along with the splenic artery and vein. The plane between the pancreas and the left kidney is then developed, and this key maneuver allows the tail of the pancreas along with the spleen to be retracted medially. The adrenal is located on the superomedial aspect of the kidney just cephalad to the tail of the pancreas and should be visible at this point unless there is a great deal of retroperitoneal fat (as is often the case in patients with Cushing syndrome). If the adrenal gland is not readily visible, laparoscopic ultrasonography should be employed to help locate it and to delineate the surrounding anatomy, particularly the upper kidney and the renal hilar vessels. If the dissection starts too low, the renal hilar vessels or the ureter could be injured.

Once the adrenal is visualized, the medial and lateral borders are usually defined by means of dissection with the hook cautery or ultrasonic coagulator and division of areolar attachments and small vessels. The dissection is then continued inferiorly to locate the adrenal vein as it obliquely exits the

inferomedial border of the gland [see Figure 8]. The inferior border of the adrenal often sits adjacent to the left renal vein, from which it can be separated by means of gentle blunt dissection and judicious use of the electrocautery.

Step 2: isolation, clipping, and division of left adrenal vein Once the adrenal vein has been visualized, it is isolated, doubly clipped, and divided. Because the adrenal vein is usually joined by the inferior phrenic vein cephalad to its junction with the renal vein, it is often necessary to clip the inferior phrenic vein again as the dissection proceeds more proximally.

Step 3: mobilization and detachment of specimen Once the left adrenal vein has been securely clipped and divided, the dissection is continued cephalad along both the lateral and the medial borders of the gland. Because of the surrounding retroperitoneal fat, it is advisable to use the ultrasonic coagulator for this part of the left-side dissection. The left adrenal is more flattened out on the superomedial aspect of the left kidney than the right adrenal; therefore, more of the kidney will be exposed during dissection in a left adrenalectomy than on the right, and one must be careful to stay close to the adrenal until the gland is off the upper kidney to avoid injuring a superior pole renal artery. Finally, the posterior and superior attachments to the diaphragm and the retroperitoneal fat are divided.

Step 4: extraction of specimen Once the gland is free, the retroperitoneum is inspected and the specimen extracted as in a right adrenalectomy. If there is any possibility that the pancreatic parenchyma may have been violated, a closed suction drain is left in place.

Retroperitoneal Approach

Retroperitoneal endoscopic adrenalectomy is typically carried out with the patient in a prone position, although it can also be done from a lateral position. In general, this technique

Figure 7 Depicted is the anatomic exposure for left adrenalectomy. (a) The splenic flexure of the colon is divided first (dotted line), and the splenorenal ligament is then divided (dashed line). (b) Shown is an intraoperative view. A = adrenal; K = kidney; S = spleen.

Figure 8 Once the left adrenal and adrenal vein are exposed, the vein is isolated and clipped. Shown are (a) a schematic representation and (b) an intraoperative view showing the left adrenal gland/tumor (A), the left adrenal vein (AV), and the phrenic vein (PV). The phrenic vein joins the left adrenal vein above its junction with the renal vein.

is more challenging to learn than transabdominal adrenalectomy, the working space is smaller, and it is easier for surgeons to become disoriented unless they have experience working in the retroperitoneum. On the other hand, the retroperitoneal approach is the most direct approach to the adrenals, and it allows surgeons to avoid having to reposition patients for bilateral adrenalectomy (if the prone position is used). It may

Figure 9 Shown is the patient position and recommended port site placement. The middle port is placed just below the tip of the 12th rib.

simplify access in patients who have previously undergone extensive upper abdominal procedures.

The technique for performing retroperitoneoscopic adrenalectomy has been well described by Walz and colleagues in over 500 cases.¹¹ The patient is in a prone position and is lying on a rectangular support that allows the abdominal wall to hang freely so that the retroperitoneum may be more easily expanded by the CO₂ gas. The initial access incision is placed just below the tip of the 12th rib, and the retroperitoneum is entered under direct visualization. The cavity is developed digitally, a second trocar is placed 4 to 5 cm laterally beneath the 11th rib, and a third port is placed medially through an incision 3 cm below the 12th rib [see Figure 9]. Alternatively, the retroperitoneal space can be developed using a balloon dissection device. It is helpful to use an adjustable blunt trocar with an inflatable balloon for the initial access site to maintain a good seal.

The retroperitoneal space should be inflated at 20 to 25 mm Hg to aid in both increasing the size of the working space and decreasing the amount of bleeding. The space is then further developed by bluntly pushing down the retroperitoneal fat beneath the diaphragm and exposing the upper pole of the kidney. The dissection then begins laterally and proceeds medially and the adrenal gland should come into view. As for the transabdominal approach, if the adrenal is difficult to locate, laparoscopic ultrasonography may be useful for defining the upper portion of the kidney and the adrenal gland and tumor.

The adrenal should first be mobilized medially, and diaphragmatic and medial arterial branches are divided. On the right side, arterial branches cross posterior to the vena cava and are divided with electrocautery or ultrasonic/bipolar energy. The adrenal vein is found by gently lifting the adrenal and exposing the medial-posterior aspect of the gland. The remaining posterior and lateral attachments are then divided. The steps in exposure of the left adrenal are similar to the right approach, but the adrenal vein is located at the medial/inferior aspect of the gland.

OPEN ADRENALECTOMY

Of the four approaches to open adrenalectomy [see *Operative Planning, Choice of Procedure, above*], the anterior transabdominal approach is the preferred method for tumors that are too large to be removed laparoscopically and for all invasive adrenal malignancies. The incision most commonly used is an extended unilateral or bilateral subcostal incision, although a midline incision is also an option [see *Figure 10*]. The extended subcostal incision yields exposure of both adrenal glands, as well as the rest of the peritoneal cavity. If necessary, it may be extended superiorly in the midline to the xiphoid to provide better upper abdominal exposure for full mobilization of the liver and access to the hepatic veins and the vena cava. The exposure obtained with this incision is sufficient for all but the most extensive adrenal malignancies. If the tumor involves the vena cava, the incision may be extended into a median sternotomy to provide access to the superior vena cava and the heart. The classic thoracoabdominal incision, which extends from the abdomen up through the seventh or eighth intercostal space and through the diaphragm, provides excellent exposure but is associated with increased incision-related morbidity and is rarely used.

Much of the exposure and dissection is the same as in a laparoscopic adrenalectomy; however, because open adrenalectomy is often employed for removal of particularly large tumors, some additional maneuvers may be necessary to achieve adequate exposure and vascular control. For exam-

ple, it may be helpful to elevate the flank with a roll or a bean-bag mattress and then flex the operating table to open up the space between the costal margin and the iliac crest. Once the abdomen is entered, exploration is carried out for the presence of metastatic disease.

Exposure of the adrenal on the right side is achieved by dividing the right triangular ligament of the liver, as in the laparoscopic approach. The hepatic flexure of the colon is also reflected inferiorly. With large tumors, a Kocher maneuver should be performed to afford better exposure of the vena cava and the renal vessels. The remainder of the dissection proceeds in much the same manner as in a laparoscopic right adrenalectomy. For suspected adrenal malignancies, a wide resection should be carried out, with removal of periadrenal fat and lymphatic tissue and any suspicious lymph nodes. For tumors that appear to involve the vena cava, vascular control of both the IVC proximal and distal to the tumor and the renal veins should be achieved before the lesion is removed.

Open left adrenalectomy entails mobilization of the splenic flexure of the colon and division of the splenorenal ligament. The spleen, the tail of the pancreas, and the stomach are reflected medially en bloc to expose the left kidney and the left adrenal. The left adrenal vein is ligated with clips or silk ties near its junction with the renal vein. The remainder of the dissection proceeds as in a laparoscopic left adrenalectomy [See *Left adrenalectomy; Step 3: mobilization and detachment of specimen, above*]. For left-side primary adrenal malignancies, periaortic lymphatic vessels and lymph nodes should be removed along with the specimen. If a large left-side tumor is invading adjacent structures, removal may require en bloc resection of the spleen, the distal pancreas, and the kidney.

Troubleshooting

INABILITY TO LOCATE THE ADRENAL

The adrenal is usually not difficult to find on the right side, where it should be visible once the right hemiliver has been mobilized. Important landmarks on that side are the IVC, which is medial to the adrenal, and the kidney, which is inferior to the adrenal. Once these structures have been identified, the location of the adrenal should be apparent. In contrast, the adrenal can be difficult to find on the left side, especially if the tumor is small or the patient is obese. To locate the left adrenal, the splenorenal ligament should be fully divided, and then the plane between the kidney and the tail of the pancreas should be developed, with the tail of the pancreas rotated medially. As dissection proceeds superiorly, the adrenal can be visually distinguished from the retroperitoneal fat by its golden-orange appearance. If the adrenal is not yet visualized at this point, laparoscopic ultrasonography should be used to verify the locations of the superior pole of the left kidney and the renal vessels. Ultrasonography should also be able to image the adrenal gland and tumor within the retroperitoneal fat [see *Figure 11*].

BLEEDING

The most effective strategy for managing bleeding during adrenalectomy is prevention. Important measures for minimizing bleeding risk include obtaining good exposure of the

Figure 10 The procedure is generally done through a unilateral or bilateral subcostal incision. For better exposure for large adrenal malignancies, the incision may be extended cephalad in the midline.

operative field and employing meticulous dissection and gentle handling of the adrenal and surrounding structures. When bleeding does occur, it may be from the adrenal veins, the adrenal gland itself, the IVC, the renal veins, the liver, the pancreas, the spleen, or the kidney. For bleeding during laparoscopic adrenalectomy, the first maneuver should be to tamponade the bleeding site with an atraumatic instrument as the bleeding will often stop with pressure. If this maneuver is successful, dissection should be directed away from the bleeding site for a while, until better exposure of the area can be obtained. Major hemorrhage from the IVC, renal veins, or arterial vessels that is not immediately controlled should be managed by prompt conversion to open adrenalectomy [see Conversion to Open Adrenalectomy, below]. Lesser bleeding may also be an indication for conversion to open adrenalectomy if it obscures the tissue planes and thereby increases the risk of inadvertent entry into the adrenal gland or tumor.

CONVERSION TO OPEN ADRENALECTOMY

Conversion to open adrenalectomy may sometimes be necessary because of bleeding, failure to progress with the dissection, or a locally invasive tumor. If the patient is in the lateral decubitus position, conversion may be accomplished by means of a subcostal incision extended into the flank. With the patient on a bean-bag mattress, the operating table can be rotated out of the straight lateral plane so that the patient comes to occupy more of a hemilateral position. If the procedure is a bilateral adrenalectomy, then either a bilateral subcostal incision or a midline incision may be employed after the patient has first been returned to more of a supine position. For this reason, it is important to extend the initial preparation and draping past the midline of the abdomen. Alternatively, if the conversion is not being done on an urgent basis because of bleeding, the port sites may be closed, and

the patient may then be moved into the supine position, repped, and redraped.

An option that may be considered before conversion to an open procedure is the use of a hand access port. A hand-assisted technique may be particularly useful for larger, noninvasive tumors that are harder to manipulate with laparoscopic instruments. The location of the incision for the hand port may vary according to the patient's body habitus; generally, however, an ipsilateral subcostal or midline location medial to the working ports allows adequate hand access while preserving visualization through the more lateral ports.

LARGE TUMORS

As surgeons become more familiar and proficient with laparoscopic adrenalectomy, the indications for removing large tumors laparoscopically have expanded. Large adrenal tumors (> 6 to 8 cm) are more difficult to remove than smaller ones because they are bulkier and more vascular and because they are harder to manipulate and retract. Accordingly, the dissection should stay extra-adrenal, and care must be exercised during manipulation to avoid entering the tumor. Surgeons should keep in mind that the larger an adrenal tumor is, the more likely it may be malignant. Laparoscopic ultrasonography should also be employed to verify that the tumor is well circumscribed and noninvasive. Surgeons who attempt to remove large adrenal tumors laparoscopically should be highly experienced in laparoscopic adrenalectomy techniques.

For large invasive adrenal malignancies, an open approach, involving a generous bilateral subcostal incision, is indicated, and the chest should be prepared in case a thoracoabdominal or median sternotomy extension proves necessary. The important principles are to obtain wide exposure of the operative field and to control all major vessels that may be involved before removing the tumor.

OBESE PATIENTS

Obese patients present a particular challenge during adrenalectomy for several reasons: initial access is more difficult, retraction and exposure are more challenging, and the copious amount of retroperitoneal fat makes it difficult to identify the adrenal and to clearly define the margins of the gland within the retroperitoneum. Our practice is to attempt to gain initial access to the peritoneal cavity by using a closed Veress needle technique. Because resting intra-abdominal pressure may be higher in obese patients, especially if they are in the lateral position, it may be necessary to increase the CO₂ pressure to 20 mm Hg temporarily until the first trocar is inserted. If it proves difficult to establish pneumoperitoneum with the Veress needle technique, the initial trocar should be placed at the umbilicus by means of an open insertion technique. The subcostal and flank ports are then inserted in the usual locations under direct vision.

On the right side, the presence of a bulky, fatty liver should be anticipated, and the locations of the port sites should be adjusted accordingly by placing them somewhat more caudad. It may be beneficial to place obese patients on a restricted-calorie diet (< 1,400 calories/day) for 2 to 3 weeks before surgery to decrease the extent of fat and thereby overall bulk of the liver. Ample time should be taken to mobilize the liver fully so that the adrenal and the IVC can be safely accessed.

Figure 11 If the left adrenal proves difficult to find, laparoscopic ultrasonography may be employed to locate the gland and the lesion within the retroperitoneal fat. This laparoscopic ultrasonogram shows an enlarged left adrenal gland secondary to metastatic squamous cell carcinoma of the lung.

On the left, the ports may be placed in the standard locations. The splenic flexure should be fully mobilized, as should the spleen and the tail of the pancreas. Laparoscopic ultrasonography is often needed to locate the gland in the retroperitoneal fat. In addition, use of an ultrasonic coagulator may facilitate division of the retroperitoneal fat.

Postoperative Care

After laparoscopic adrenalectomy, most patients are admitted to a regular nursing unit, although some patients with pheochromocytomas will need to undergo a short stay in the intensive care unit for invasive monitoring. Patients are started on clear liquids once they are awake and alert, and the diet is advanced as tolerated. The urinary catheter is usually removed on postoperative day 1. Intravenous analgesia is switched to oral analgesia as soon as the patient can tolerate oral feeding. A complete blood count is obtained on postoperative day 1 in all patients, and electrolyte levels are monitored in patients with aldosteronomas and hypercortisolism. Patients with Cushing syndrome should be given stress doses of steroids perioperatively and should be discharged on a maintenance prednisone dosage of 10 to 15 mg/day in divided doses. These patients should be advised that it may take 6 to 12 months or longer for the contralateral adrenal to recover to the point where prednisone can be discontinued. Patients undergoing bilateral adrenalectomy will need lifelong replacement therapy with a glucocorticoid (e.g., prednisone) and a mineralocorticoid (e.g., fludrocortisone acetate 0.1 mg/day).

Postoperative management of hypertensive medications depends on the pathology of the underlying adrenal lesion. In patients with aldosteronomas, spironolactone is stopped immediately after adrenalectomy, and the other antihypertensive agents are usually continued while blood pressure is monitored closely on an outpatient basis; further medication reductions are made as clinically warranted. In most patients with Cushing syndrome, antihypertensive medications are continued, whereas in most patients with pheochromocytomas, they are not. In both sets of patients, however, close outpatient monitoring of blood pressure should be carried out in the early postoperative period. Adrenalectomy can have a dramatic impact on hypertensive control and can lead to hypotension if medications are not appropriately adjusted.

In most routine cases, patients can be discharged within 24 hours after laparoscopic adrenalectomy, although some patients require longer in-hospital observation for blood pressure monitoring, for adjustment of steroid replacement therapy, or for resumption of a regular diet. After open adrenalectomy, resumption of an oral diet occurs later, and postoperative hospital stays of 4 to 5 days are more typical.

After discharge, patients are seen in the clinic within 2 to 3 weeks for a wound check, blood pressure evaluation, and a review of antihypertensive medications. In patients who underwent adrenalectomy for an aldosteronoma, electrolyte levels and the creatinine concentration should be checked. In patients who underwent adrenalectomy for pheochromocytoma, yearly clinical and biochemical follow-up is indicated, with measurement of either plasma levels of fractionated

metanephrines or urine levels of catecholamines and metanephrines. In selected patients on steroid replacement therapy who are proving difficult to wean from prednisone, an ACTH stimulation test may be necessary to assess the responsiveness of the pituitary-adrenal axis.

Complications

It appears that laparoscopic adrenalectomy has a major advantage over open adrenalectomy in terms of the incidence of postoperative complications. In a meta-analysis of 98 adrenalectomy series reported between 1980 and 2000, the overall complication rate was 10.9% with laparoscopic procedures and 25.2% with open procedures.¹² This difference between the complication rates was primarily attributable to the occurrence of fewer wound, pulmonary, and infectious complications in the laparoscopic series. The most common complication of laparoscopic adrenalectomy is bleeding, which was reported in 4.7% of patients from the series reviewed in the meta-analysis. Bleeding is also the most common reason for conversion to open adrenalectomy; however, major bleeding that leads to transfusion is relatively uncommon. The risk of bleeding can be minimized by obtaining meticulous hemostasis, taking care not to grasp the adrenal gland, and handling tissue gently. If bleeding does occur, the prudent course of action is to maintain pressure on the bleeding source while obtaining better exposure or even starting the dissection in another area rather than to resort to indiscriminate use of clips or electrocautery. The surgeon must be prepared to convert rapidly to an open procedure should major hemorrhage occur.

Other potential complications of adrenalectomy (either laparoscopic or open) include injury to the tail of the pancreas (with resultant pancreatic leakage or pancreatitis), injury to the diaphragm, and pneumothorax. Wound infections are uncommon with laparoscopic adrenalectomy. Trocar site hernias are infrequent as well, provided that the fascia is closed at all port sites that are 10 mm or larger. Deep vein thrombosis occurs in 0.8% of cases, and pulmonary embolism in 0.5%.¹² Pneumatic compression stockings should be used perioperatively to minimize the risk of venous thromboembolism. Renovascular hypertension from injury to the renal artery has also been reported.^{13,14} Recently, severe high-grade complications of adrenalectomy have been described, including porta hepatis and hepatic artery injuries that resulted in liver transplantation and injuries to the renal vessels and to the ureter that resulted in a loss of renal function.¹⁵ The operative mortality associated with laparoscopic adrenalectomy is about 0.3%.

Several cases of local or regional tumor recurrence have been reported after laparoscopic adrenalectomy. In most of these cases, the tumors removed were either suspected or unsuspected adrenal malignancies, and the extensive nature of the recurrences was probably related to aggressive tumor biology rather than to the minimally invasive surgical technique. In some of these cases, however, the pattern of recurrence, characterized by the development of multiple intraperitoneal or port site metastases, suggested that laparoscopic dissection and pneumoperitoneum might have contributed to tumor spread.¹⁶⁻¹⁹ One group treated three patients

for recurrent pheochromocytomatosis that developed after laparoscopic adrenalectomy.²⁰ These patients were found to have multiple small tumor nodules in the adrenalectomy bed during open reoperation after removal of apparently benign pheochromocytomas. Fragmentation of the tumor and excessive tumor manipulation during the laparoscopic dissection were considered the probable mechanisms of tumor recurrence.

These reports highlight the need for caution in approaching large, malignant, or potentially malignant adrenal tumors. Surgeons who attempt a laparoscopic approach in this setting should be highly experienced in laparoscopic adrenalectomy techniques, and the tumor should be well circumscribed and not locally invasive. The use of a hand port may be a valuable adjunct to resection in these cases. Regardless of the specific surgical approach followed, wide excision of the lesion along with the surrounding periadrenal fat is crucial for minimizing recurrence rates in this population.

Outcome Evaluation

The safety and efficacy of laparoscopic adrenalectomy for the removal of small, benign adrenal tumors have been clearly established. Rates of conversion to open adrenalectomy in high-volume centers have ranged from 3 to 13%, and operating times have averaged 2 to 3 hours.^{10,13,21–26} Most patients are now discharged from the hospital within 24 to 48 hours after operation. Although no prospective, randomized trial comparing laparoscopic with open adrenalectomy has been carried out, several retrospective studies have consistently shown that the laparoscopic approach is associated with

decreased pain, a shorter hospital stay, and a faster recovery.^{27–30} Complication rates have also been low, and, overall, complications appear to be less common than with open adrenalectomy.¹²

The results of a laparoscopic approach in patients with large (> 6 cm) adrenal tumors or malignant primary or metastatic adrenal lesions have been reviewed³¹; generally, the conversion rates for large or malignant tumors have been higher than those reported in other laparoscopic adrenalectomy series. Overall, tumor recurrence rates after laparoscopic adrenalectomy have been low.^{32–36} In one series, however, local or regional tumor recurrence developed in three of five patients with adrenocortical carcinomas that were treated laparoscopically.³⁷ Other groups have also published anecdotal reports of local tumor recurrences after resection of unsuspected adrenal carcinomas.^{16–19} In another series from M. D. Anderson Cancer Center of patients with local recurrence after adrenalectomy, peritoneal carcinomatosis developed in five of six patients (83%) after laparoscopic resection compared with only 8% of patients with local recurrences after open adrenalectomy.³⁸ Whether the recurrences in these reported cases were related primarily to the surgical technique employed or to the underlying tumor biology is unclear. It would appear, therefore, that in most cases, primary adrenal malignancies are best approached in an open fashion unless the tumor is small and well circumscribed and the surgeon is highly experienced.

Financial Disclosures: None Reported.

27 REPAIR OF VENTRAL ABDOMINAL WALL HERNIAS

*Karem Harth, MD, MHS, and Michael J. Rosen, MD, FACS**

The repair of noninguinal abdominal wall defects is one of the most common procedures performed by general surgeons. With greater than 200,000 annual operations, there is little agreement or consensus in the literature as to the ideal approach for this difficult problem. In the past, personal recollections and single-center series were the principal data sources that surgeons relied on in choosing the optimum treatment strategy for a patient. In recent years, fortunately, population-based studies have provided better data on the true failure rates associated with the various herniorrhaphies.

In this chapter, we describe different operations for noninguinal abdominal wall hernias. In the repair of abdominal wall defects, the surgeon must consider a multitude of factors to identify the appropriate surgical technique to accomplish the reconstructive goals. Given that a full spectrum of patients develop hernias, it is unlikely that any single technique will be appropriate for all hernias. An individualized approach is needed to find the appropriate procedure. To do this all surgeons must familiarize themselves with important factors such as patient age, comorbidities, physiologic status, defect size, available local tissue and presence of contamination. Likewise, an understanding of the available reconstructive techniques and an honest assessment of the surgeon's ability to perform each of these techniques should guide the surgeon in establishing the most appropriate repair for the patient. A well-known surgical dictum states that when numerous different operations exist to treat the same disease, the perfect procedure does not exist. This dictum does not hold true for abdominal wall herniorrhaphy, however. Because the disease is so heterogeneous, different techniques are needed to address individual patients' needs.

Epidemiology

In the United States, approximately 1,000,000 abdominal wall herniorrhaphies are performed each year, of which 750,000 are for inguinal hernias, 166,000 for umbilical hernias, 97,000 for incisional hernias, 25,000 for femoral hernias, and 76,000 for miscellaneous hernias.¹ The prevalence of abdominal wall hernias is difficult to determine as the wide range of published figures in the literature illustrates. The major reasons for this difficulty are (1) the lack of standardization in how ventral hernias are defined; (2) the

inconsistency of the data sources used (which include self-reporting by patients, audits of routine physical examinations, and insurance company databases, among others); (3) the subjectivity of physical examination, even when performed by trained surgeons; and (4) the lack of long-term follow-up on all patients with prior surgery at risk for developing incisional hernias.

The incidence of the most common type of ventral hernia, incisional hernia, depends on how the condition is defined. The best definition of incisional hernia is any abdominal wall gap, with or without a bulge that is perceptible on clinical examination or diagnostic imaging within 1 year after the index operation. A definition that requires the presence of a visible bulge will lead to underestimation of the true incidence of the condition. The reported incidence of incisional hernia after a midline laparotomy ranges from 3 and 20% and doubles if the index operation was associated with infection. Incisional hernias are most common after midline and transverse incisions but are also well documented after paramedian, subcostal, McBurney (gridiron), and Pfannenstiel incisions.² An analysis of 11 publications dealing with ventral hernia incidence after various types of incisions concluded that the risk was 10.5% for midline incisions, 7.5% for transverse incisions, and 2.5% for paramedian incisions.³ A randomized controlled trial comparing midline versus transverse incisions did not find a difference in analgesia use, pulmonary complications, or hernia recurrence after 1 year but did find increased wound infections in the transverse incision group.⁴ Muscle-splitting incisions probably have a lower incidence of incisional hernias, but such incisions restrict access to the abdominal cavity. Given similar recurrence rates between midline and transverse incisions, the operative visualization required should dictate the choice of incision. Most incisional hernias are detected within 1 year of surgery; the most common cause is believed to be separation of aponeurotic edges in the early postoperative period. The male-to-female incidence ratio is 1:1, even though early evisceration is more common in males.

At present, little information is available on the risk of major complications arising from untreated noninguinal abdominal wall hernias. The main reason for this scarcity of data is that surgeons are taught, first, that all hernias, even asymptomatic ones, should be repaired at diagnosis to prevent potential strangulation or bowel obstruction and, second, that herniorrhaphy becomes more difficult the longer the repair is delayed. As a result, it is difficult to find a whole population in which at least some of the members do not routinely have their hernias repaired regardless of symptoms. In these circumstances, accurate estimates of the natural history of the disease are impossible.

* The authors and editors gratefully acknowledge the contributions of the previous authors, Robert J. Fitzgibbons Jr, MD, FACS, Alan T. Richards, MD, FACS, and Thomas H. Quinn, PhD, to the development and writing of this chapter.

Table 1 Zollinger Classification System for Ventral Abdominal Wall Hernias

Type	Examples
Congenital	Omphalocele Gastroschisis Umbilical (infant)
Acquired	Midline Diastasis recti Epigastric Umbilical (adult, acquired, paraumbilical) Median Supravesical (anterior, posterior, lateral) Paramedian Spigelian Interparietal
Incisional	Midline Paramedian Transverse Special operative sites
Traumatic	Penetrating, autopenetrating* Blunt Focal, minimal injury Moderate injury Extensive force or shear Destructive

*Penetration from host tissue such as bone.

Classification of Ventral Hernias

A classification system for abdominal wall hernias outside the groin has been proposed by Zollinger [see Table 1].⁵ Ventral incisional hernias are common enough to warrant their own discrete classification system. The scheme most often used for categorizing incisional hernias [see Table 2] was the result of a 1998 consensus conference held in conjunction

Table 2 Classification System for Incisional Hernias

Parameter	Categories
Location	Vertical Midline, above or below umbilicus Midline, including umbilicus Paramedian Transverse Above or below umbilicus Crosses midline Oblique Above or below umbilicus Combined

Recurrence	Primary Multiply recurrent Stratification for type of previous repair
Reducibility	Yes Obstruction No obstruction No Obstruction No obstruction
Symptoms	Asymptomatic Symptomatic

*Difficult to measure consistently.

with the European Hernia Society's annual congress.⁶ This system is important in that it affords investigators a reliable means of comparing results between one procedure and another or between one center and another.

Abdominal Wall Anatomy

The skin of the lower anterior abdominal wall is innervated by anterior and lateral cutaneous branches of the ventral rami of the seventh through 12th intercostal nerves and by the ventral rami of the first and second lumbar nerves. These nerves course between the lateral flat muscles of the abdominal wall and enter the skin through the subcutaneous tissue.

The first layers encountered beneath the skin are the Camper and Scarpa fasciae in the subcutaneous tissue. The only significance of these layers is that when sufficiently developed, they can be reapproximated to provide another layer between a repaired abdominal wall and the outside. The major blood vessels of this superficial fatty layer are the superficial inferior and superior epigastric vessels, the intercostal vessels, and the superficial circumflex iliac vessels (which are branches of the femoral vessels). These vessels run superficial to the Scarpa fascia.

The external oblique muscle is the most superficial of the great flat muscles of the abdominal wall [see Figure 1]. This muscle arises from the posterior aspects of the lower eight ribs and interdigitates with both the serratus anterior and the latissimus dorsi at its origin. The posterior portion of the external oblique muscle is oriented vertically and inserts on the crest of the ilium. The anterior portion of the muscle courses inferiorly and obliquely toward the midline and the pubis. The muscle fibers give way to form its aponeurosis, which occurs well above the inguinal region. The obliquely arranged anterior inferior fibers of the aponeurosis of the external oblique muscle fold back on themselves to form the inguinal ligament, which attaches laterally to the anterior superior iliac spine. In most persons, the medial insertion of the inguinal ligament is dual: one portion of the ligament inserts on the pubic tubercle and the pubic bone, whereas the other portion is fan shaped and spans the distance between the inguinal ligament proper and the pectineal line of the pubis. This fan-shaped portion of the inguinal ligament is called the lacunar ligament. It blends laterally with the Cooper ligament (or, to be anatomically correct, the pectineal ligament). The more medial fibers of the aponeurosis of the external oblique muscle divide into a medial crus and a lateral crus to form the external or superficial inguinal ring, through which the spermatic cord (in females, the round ligament) and branches of the ilioinguinal and genitofemoral nerves pass. The rest of the medial fibers insert into the linea alba after contributing to the anterior portion of the rectus sheath.

Beneath the external oblique muscle is the internal oblique muscle. The fibers of the internal oblique muscle fan out following the shape of the iliac cres so that the superior fibers course obliquely upward toward the distal ends of the lower three or four ribs, whereas the lower fibers orient themselves inferomedially toward the pubis to run parallel to the external oblique aponeurotic fibers. These fibers arch over the round ligament or the spermatic cord, forming the superficial part of the internal (deep) inguinal ring.

Figure 1 Shown are the great flat muscles of the abdominal wall, depicting the relationship of the great muscles to the groin.

Beneath the internal oblique muscle is the transversus abdominis. This muscle arises from the inguinal ligament, the inner side of the iliac crest, the endoabdominal fascia, and the lower six costal cartilages and ribs, where it interdigitates with the lateral diaphragmatic fibers. The medial aponeurotic fibers of the transversus abdominis contribute to the rectus sheath and insert on the pecten ossis pubis and the crest of the pubis, forming the falx inguinalis. Infrequently, these fibers are joined by a portion of the internal oblique aponeurosis; only when this occurs is a true conjoint tendon formed.⁷

Aponeurotic fibers of the transversus abdominis also form the structure known as the aponeurotic arch. It is theorized that contraction of the transversus abdominis causes the arch to move downward toward the inguinal ligament, thereby constituting a form of shutter mechanism that reinforces the weakest area of the groin when intra-abdominal pressure is raised. The area beneath the arch varies. Many authorities believe that a high arch, resulting in a larger area from which the transversus abdominis is, by definition, absent, is a predisposing factor for a direct inguinal hernia. The transverse aponeurotic arch is also important because the term is used by many authors to describe the medial structure that is sewn to the inguinal ligament in many of the older inguinal hernia repairs.

The rectus abdominis forms the central anchoring muscle mass of the anterior abdomen. It arises from the fifth through seventh costal cartilages and inserts on the pubic symphysis

and the pubic crest. It is innervated by the seventh through 12th intercostal nerves, which laterally pierce the aponeurotic sheath of the muscle. The semilunar line is the slight depression in the aponeurotic fibers coursing toward the muscle. In a minority of persons, the small pyramidalis muscle accompanies the rectus abdominis at its insertion. This muscle arises from the pubic symphysis. It lies within the rectus sheath and tapers to attach to the linea alba, which represents the conjunction of the two rectus sheaths and is the major site of insertion for three aponeuroses from all three lateral muscle layers. The line of Douglas (i.e., the arcuate line of the rectus sheath) is formed at a variable distance between the umbilicus and the inguinal space because the fasciae of the large flat muscles of the abdominal wall contribute their aponeuroses to the anterior surface of the muscle, leaving only transversalis fascia to cover the posterior surface of the rectus abdominis.

The innervation of the anterior wall muscles is multifaceted. The seventh through 12th intercostal nerves and the first and second lumbar nerves provide most of the innervation of the lateral muscles, as well as of the rectus abdominis and the overlying skin. The nerves pass anteriorly in a plane between the internal oblique muscle and the transversus abdominis, eventually piercing the lateral aspect of the rectus sheath to innervate the muscle therein. The external oblique muscle receives branches of the intercostal nerves, which penetrate the internal oblique muscle to reach it. The anterior ends of the nerves form part of the cutaneous innervation of the abdominal wall. The first lumbar nerve divides into the

ilioinguinal nerve and the iliohypogastric nerve [see Figure 2]. These important nerves lie in the space between the internal oblique muscle and the external oblique aponeurosis. They may divide within the psoas major or between the internal oblique muscle and the transversus abdominis. The ilioinguinal nerve may communicate with the iliohypogastric nerve before innervating the internal oblique muscle. The ilioinguinal nerve then passes through the external inguinal ring to run parallel to the spermatic cord, whereas the iliohypogastric nerve pierces the external oblique muscle to innervate the skin above the pubis. The cremaster muscle fibers, which are derived from the internal oblique muscle, are innervated by the genitofemoral nerve. There can be considerable variability and overlap.

The blood supply of the lateral muscles of the anterior wall comes primarily from the lower three or four intercostal arteries, the deep circumflex iliac artery, and the lumbar arteries. The rectus abdominis has a complicated blood supply that derives from the superior epigastric artery (a terminal branch of the internal thoracic [internal mammary] artery), the inferior epigastric artery (a branch of the external iliac artery), and the lower intercostal arteries. The lower intercostal arteries enter the sides of the muscle after traveling between the oblique muscles; the superior and the inferior epigastric arteries enter the rectus sheath and anastomose near the umbilicus. During the creation of skin flaps for component separation, preservation of this region has been described as a way to decrease complications such as skin flap necrosis.⁸

The endoabdominal fascia is the deep fascia covering the internal surface of the transversus abdominis, the iliacus, the

psoas major and minor, the obturator internus, and portions of the periosteum. It is a continuous sheet that extends throughout the extraperitoneal space and is sometimes referred to as the wallpaper of the abdominal cavity. Commonly, the endoabdominal fascia is subclassified according to the muscle being covered (e.g., iliac fascia or obturator fascia).

Between the transversalis fascia and the peritoneum is the preperitoneal space. In the midline behind the pubis, this space is known as the space of Retzius; laterally, it is referred to as the space of Bogros. The preperitoneal space is of particular importance for surgeons because several hernia repairs (see below) are performed in this area. The inferior epigastric vessels, the deep inferior epigastric vein, the iliopubic vein, the rectus vein, the retropubic vein, the communicating rectusioepigastric vein, the internal spermatic vessels, and the vas deferens are all encountered in this space.⁹

Choice of Prosthetic Material

For most abdominal wall hernias, the procedure of choice includes the use of a prosthesis. A multitude of prosthetic grafts are currently available, all with their own unique advantages and disadvantages. Most prosthetic grafts can be categorized as derived from polypropylene, polyester, or polytetrafluoroethylene (PTFE). Uscher is credited with developing polypropylene mesh and introduced it in the early 1960s.¹⁰ Since their introduction, there has been an increase in use. An American population-based study of approximately 11,000 patients reflected an increase in mesh use for hernia repair from 35% in 1987 to 65% by 1999.¹¹ A detailed discussion comparing various prosthetic materials is beyond the scope of this chapter; however, some general statements may be made.

The use of mesh presupposes a situation in which the prosthesis can be isolated from contact with intra-abdominal viscera by one or more layers of human tissue (e.g., peritoneum). In situations where contact with intra-abdominal viscera cannot be avoided, a standard mesh prosthesis should not be used as it causes a significant fibroblastic response and risks subsequent bowel-related complications. Either the prosthesis should be composed of a nonmesh material, such as expanded polytetrafluoroethylene (ePTFE), or a dual-layer prosthesis should be used, with a standard plastic mesh on the side facing the abdominal wall (to encourage an intense fibroplastic response) and an adhesion barrier of some type coating the peritoneal side. Numerous dual-sided prosthetics, incorporating a variety of adhesion barriers, are now available [see Table 3]. It has consistently been shown that when these materials are used, adhesions are not only less common but also less tenacious than when mesh alone is used in an intra-peritoneal position. Often bowel adhesions can be easily wiped from the peritoneal surface of a dual-layer prosthesis with gentle blunt traction, in sharp contrast to the typically tedious and sometimes impossible dissection of bowel loops from an unprotected mesh prosthesis placed directly on the viscera. Although all of the dual-layer prostheses currently on the market are approved for decreasing adhesions to the adhesion barrier side, no manufacturer has sought approval for complete prevention of adhesions. Consequently, the

long-term effects of these less severe (but still present) adhesions are unknown; further study is required to address this issue.

At present, there is some controversy regarding the weight of polypropylene mesh used in abdominal wall hernia repairs, although the controversy almost certainly applies to the other types of mesh prosthesis as well. Data from randomized studies indicate that use of a lightweight polypropylene mesh compared with standard mesh results in similar long-term pain in incisional hernia repair.¹² When used in the setting of inguinal hernia repair, two randomized controlled trials have shown varied results with regard to pain control.^{12–14} In the randomized controlled multicenter trial for incisional hernia repair, no difference in recurrence was found at 24 months in the lightweight (17%) versus the standard (7%) mesh repair (*p* value .052). However, a closer look at their methodology reveals important considerations. After 24 months, there was approximately 20% loss of follow-up for each lightweight and standard mesh group, which may underpower their ability to detect a statistically significant difference. Also, technical variables may have impacted the observed hernia recurrence rates, including poor cephalad mesh tissue coverage and use of absorbable sutures to secure the mesh and close the midline. Having recognized these important issues, newer trials have been designed to control for these factors and are currently in progress.

Lighter-weight mesh also addresses the theoretical concern about the possible carcinogenic effects of polypropylene, as has been suggested by experimental studies in rats, although it should be kept in mind that there has never been a documented case of a sarcoma developing in a human being as a result of an inguinal hernia prosthesis.¹⁵ To illustrate the difference between a lightweight mesh and a normal one, a 7.5 × 15 cm piece of polypropylene mesh (Prolene, Ethicon, Inc., Somerville, NJ) weighs about 80 g/m², whereas a similarly sized piece of a polypropylene–poliglecaprone 25 (Monocryl, Ethicon, Inc.) lightweight mesh (UltraPro, Ethicon, Inc.) weighs less than 30 g/m² after absorption of the poliglecaprone 25 component.

North American surgeons have been slow to accept the use of lightweight mesh for inguinal hernia repair, fearing a higher recurrence rate.^{12,16} Many also have some concerns about possible bias in the data, noting that the research supporting the use of lightweight mesh has been almost exclusively funded by industry. Nevertheless, the randomized trials mentioned earlier cannot be entirely discounted. Most likely, lightweight mesh will have a role in abdominal wall reconstruction in appropriately selected patients. The limits of this mesh are currently being evaluated in several long-term studies.

The potential for mesh infection is also a topic with significant research in hernia surgery, particularly as mesh infection has been diagnosed as late as 39 months following implantation.¹⁷ Inherent mesh characteristics can influence the likelihood of mesh infection and the ability to treat this complication. The hydrophobicity, porosity, and weave characteristics are all important factors that affect the outcomes of mesh sepsis. Although some macroporous mesh (polypropylene, polyester) infections can be treated with local measures, it is very rare to salvage an infected microporous (PTFE) prosthetic. Several nonrandomized studies have evaluated risk factors for surgical site infection as they relate to different mesh morphologies in the setting of laparoscopic or open incisional hernia repair. Although most studies are not designed with infection as the primary end point, some noteworthy trends can be generalized. Studies have found greater potential for infection with ePTFE mesh compared with lower rates with monofilament polypropylene mesh.^{17,18} Polyester-based materials have varied results in the literature, with some studies showing acceptable rates of infection.^{19–21} The continued understanding of how intrinsic mesh characteristics relate to future risk of infection will likely lead to parallel advances in the biomaterial industry.

The quest for the perfect mesh has driven the introduction of a wide variety of synthetic meshes into the market since the 1960s. More recently, one of the fastest growing markets for hernia repair is that for prosthetics derived from animal or human tissue called biologics [see Table 4]. The widespread use of these grafts in abdominal wall reconstruction has resulted in close to 400 million dollars spent on biologic grafts in the United States in 2007. The market value for these biomaterials is predicted to increase to 500 million dollars by 2013 and far exceed the rate of growth for synthetic materials. These expensive materials are reported to be superior to synthetic meshes given their hypothetical ability to resist infection and biodegrade over time, leaving behind only native, regenerated collagen. The evidence behind this reported advantage is lacking, and research regarding their performance is mainly limited to clean cases.

The sources of biologic grafts may be different (human, porcine, bovine), their processing techniques are varied (crosslinked and noncrosslinked), and so are their sterilizing techniques (γ radiation, ethylene oxide gas sterilization, or nonsterilization). Biologic grafts are designed to serve as an extracellular matrix scaffold for neovascularization and new collagen ingrowth, promoting vessel ingrowth and eventual remodeling of tissue to resemble the native type. The incorporation of native tissue and vessels into these bioscaffolds gives them the theoretical advantage of resisting bacterial proliferation as cells such as macrophages and antibiotics are able to reach the bacteria. Much like synthetic mesh, the best

practices of biologic graft placement are unknown and highly varied at this time. The use of biologic materials is a relatively new area in hernia surgery, and further animal and clinical studies are needed to answer many important questions. Currently, these grafts appear to tolerate clean contaminated cases, but their long-term durability and role in hernia recurrence are largely unknown. Although biologic prostheses are much more expensive than synthetic prostheses, the long-term cost-effective benefits of using these materials, particularly in contaminated cases, may be beneficial. More recently, newer absorbable synthetics that do not biodegrade for several months (unlike polyglactin 910 [Vicryl, Ethicon, Inc.] mesh) have been introduced into the market and proposed as less costly alternatives to biologic grafts. However, few data exist for these new materials. Further studies are required before their exact place in the armamentarium of the abdominal wall hernia surgeon can be determined.

Incisional Hernia Repair

Incisional hernias occur as a complication of previous surgery. As noted, their incidence depends on how they are defined [see Epidemiology, above]. In the literature, the incidence of incisional hernia ranges from 3 to 12% of all laparotomy incisions and largely depends on several underlying patient characteristics.^{2,22} Postoperative wound infections result in a much higher incidence of incisional hernia formation.

The root cause of incisional hernia is undoubtedly multifactorial. Technical factors such as slippage of knots, suture fractures, excessive tension, or rapidly absorbable sutures can result in incisional hernia formation.²³ However, certain patients with collagen metabolism disorders are also prone to incisional hernia formation. In particular, patients with aortic aneurysms and diverticular disease likely have systemic disorders of collagen metabolism [see Table 5]. Nevertheless, the importance of careful attention to technical detail in the closure of any abdominal incision should not be minimized.

Surgeons' practices in closing laparotomies tend to be far more dependent on tradition and often lack high-quality level I scientific evidence.²⁴ Techniques of continuous versus interrupted closure or use of absorbable versus nonabsorbable suture are approaches without consensus as shown by review of the literature and a recent survey of general surgeons performing hernia repair.²⁵ The authors found that a strong consensus (treatment applied in > 95% of cases) regarding closure of midline wounds was not achieved. A meta-analysis of randomized controlled trials evaluating different midline closure techniques concluded that nonabsorbable suture in a continuous fashion led to lower rates of incisional hernia.²⁴ A follow-up meta-analysis with similar criteria found no difference in hernia recurrence between slowly absorbable suture versus nonabsorbable suture.²⁶ This study, however, found higher rates of suture-related sinus drainage and pain in the nonabsorbable group and found no difference in hernia recurrence when continuous versus interrupted techniques were compared. The most recent randomized controlled trial evaluating interrupted rapidly absorbable suture (polyglactin 910) with continuous slowly absorbing suture (polydioxanone [PDS, Ethicon, Inc. and MonoPlus, B. Braun, Germany]) was unable to detect a difference in hernia recurrence between the groups, although it appeared that polydioxanone had the least overall rates of recurrence.²⁷

Despite the varied literature, some general recommendations can be made on the basis of current data and experience. Although a general consensus precludes identification of a "gold standard" for midline closure, a continuous

Genetic
Molecular

polydioxanone suture, with stitches placed 1 cm from the fascial edge and 1 cm apart, does as well in terms of hernia recurrence as a continuous monofilament polypropylene suture. The long-term advantages of polydioxanone are its decreased sinus formation and chronic pain.

Other factors should be considered in the closure of midline wounds. To prevent excessive tension, the length of the suture should be four times the length of the wound.²⁴ Monofilament sutures perform better than braided sutures because bacteria tend to form colonies among the braids of multifilament sutures.^{28–31} Nonabsorbable suture material has the advantage of greater longevity than absorbable suture material but is more likely to result in sinus formation and chronic wound pain.^{3,24} The incidence of wound infection is not affected by the suture material or the closure method.

Various patient-related risk factors for incisional hernia have been identified [see Table 6].^{32,33} Although some controversy remains, the current consensus is that there appears to be an association between these comorbid conditions and the incidence of incisional hernia. The type of wound incurred also plays a role. Incisional herniation appears most common after midline laparotomies, especially upper midline incisions, and less common after transverse or oblique incisions.² An analysis of 11 publications addressing ventral hernia incidence after various types of incisions found the risk to be 10.5% for midline incisions, 7.5% for transverse incisions, and 2.5% for paramedian incisions.³ A recent randomized controlled trial evaluating midline versus transverse incisions with a secondary end point of hernia recurrence found no difference between either approach at the 1-year follow-up.⁴ However, the authors noted that to truly detect a difference in hernia recurrence between these approaches, nearly 2,500 patients would be required in each group. Thus, the authors recommend that surgeons select the incision that ultimately yields the best exposure.

Over longer periods, the incidence of incisional hernia recurrence increases, with the majority developing in the first 4 years after the sentinel operation.³⁴ It is anticipated that as the use of minimally invasive surgical techniques increases, the incidence of incisional hernia will drop. Hernias developing within 10 and 12 mm port sites are well documented; hernias in 5 mm port incisions are rare. At present, long-term

data on the incidence and natural history of port-site hernias are lacking.³⁵

Genetic factors are important as well: familial predisposition to incisional hernia has long been recognized as contributory by surgeons caring for patients with this condition. An increased incidence of incisional herniation in patients with certain connective tissue diseases (e.g., osteogenesis imperfecta, Marfan syndrome, and Ehlers-Danlos syndrome) has been documented. Finally, the molecular details of incisional hernia causation are now beginning to be appreciated. Type 1 to type 3 collagen imbalance, abnormal matrix metalloproteinase (MMP) expression, and growth factor relations are among the molecular-level processes that are currently under intense scrutiny by the scientific community with regard to the etiology of incisional hernia.

Not every patient who presents to a surgeon with an incisional hernia is necessarily a candidate for surgical repair. There are three indications for operation: (1) a hernia that is symptomatic, causing pain, discomfort, or changes in bowel habits; (2) a hernia resulting in an unsightly bulge that affects the patient's quality of life; and (3) a hernia that poses a significant risk of bowel obstruction (e.g., a large hernia with a narrow neck). However, the natural history of slow continued growth of incisional hernias attributable to increased intra-abdominal pressure should be taken into consideration. In young patients with moderate-size hernias, a nonoperative approach can result in a more complex reconstruction in the future if the hernia becomes larger and more symptomatic.

The repair of incisional hernias is often more complicated than inguinal repair for several reasons. By definition, all incisional hernias are reoperative cases, demanding careful adhesiolysis and delineation of the anatomy. Additionally, it is important that the patient and the surgeon have a clear understanding of the goals of the procedure. For all ventral hernias, the surgeon must reduce the hernia contents into the abdominal cavity and prevent future migration and recurrent herniation. This can be performed by simply patching a defect with prosthetic material or can similarly be accomplished by reconstructing a functional dynamic abdominal wall via medialization of the rectus muscles with potential prosthetic reinforcement. Each of these approaches has its own unique merits, and careful consideration should be given to each technique to find the ideal reconstruction for the patient.

Open Ventral Hernia Repair: Operative Technique

NONPROSTHETIC REPAIRS

Historically, primary suture repair was the procedure of choice for most incisional hernias; prosthetic material was reserved for particularly difficult cases as a result of the perceived risks of this material. In the latter part of the 20th century, large population-based studies changed this way of thinking, revealing that primary suture repair was associated with a much higher recurrence rate than most surgeons would have assumed (25 to 55%).⁶ Studies comparing primary suture with prosthetic repair showed that the recurrence rate was dramatically lower with the latter.³⁶ In a randomized controlled study from the Netherlands, even small incisional

hernias (< 10 cm²) had a recurrence rate of 67% when primary suture repair was employed.³⁷ Additionally, a recent Cochrane review of available randomized trials with a minimum of 1-year follow-up showed that suture repair had a recurrence risk of 85% greater compared with mesh repair.³⁸

PROSTHETIC REPAIRS

The use of prosthetic material to reduce tension in ventral hernia repair was first described in the 1950s.¹⁰ Since its introduction, inclusion of mesh in ventral hernia repair has unquestionably reduced the recurrence rate. With the addition of synthetic prosthetics to the surgeon's armamentarium, the debate for the ideal surgical approach for placing mesh continues unanswered. Although each approach has its ardent supporters, there are few data carefully evaluating each approach in appropriately designed comparative trials. Given the lack of definitive data, it is difficult to provide a clear, concise recommendation as to the ideal approach. However, certain general guidelines can be stated. Basically, three options exist for mesh placement: as an overlay (onlay), as a bridge secured to the fascial edges (inlay), or as an underlay (sublay) in either a retrorectus, preperitoneal, or intraperitoneal position [see Figure 3].

A mesh overlay (onlay) may be placed on top of any of a variety of simple repairs. Although some series have reported that this approach yields acceptable results in selected patients, most surgeons feel that it offers little advantage over the simple repair that the prosthesis overlies and that it is typically associated with a similarly disappointing recurrence rate of up to 25%.^{6,39} Additional disadvantages of placing prosthetic material in this position are its close proximity to the skin with higher potential for exposure following a wound infection and the wide skin undermining needed to achieve broad coverage.⁴⁰ Wound complications are estimated to be between 4 and 26% using this approach secondary to the creation of skin flaps necessary to secure the mesh.⁶ Proponents of this technique claim an advantage of the mesh not being placed in direct contact with the abdominal viscera. However, if the midline fascial closure breaks down, the bowel will interact with an often unprotected macroporous mesh.

Prosthetic inlay (bridging) repair became popular in the 1990s, in keeping with the tension-free ideal for inguinal herniorrhaphy. The principle underlying this technique is that for a prosthetic repair to be truly tension free, the defect should be bridged. Unfortunately, the abdominal wall likely experiences different forces during activity than the groin. In fact, a true tension-free repair might not be ideal in the anterior abdominal wall. Given that contraction of the rectus and lateral abdominal wall muscles that are not joined at the linea alba results in lateral displacement, a constant force of separation is placed on the prosthetic. Coupled with the incidence of some shrinkage of most prosthetics, this has resulted in a predictably high recurrence rate at the mesh–native tissue interface.^{41,42} Following a systematic review of 119 studies on ventral hernia repair, the inlay technique was found to have the highest reported rate of recurrence, largely attributed to poor mesh fixation and inadequate lateral overlap.⁴² The recurrence rate is especially high in obese patients and greater with increasing hernia size. In a study from the Netherlands,

Figure 3 Incisional hernia repair. Depicted are three potential positions for placement of a prosthesis for repair of ventral abdominal wall defects.

the recurrence rate even with mesh repairs (mostly onlay and inlay) was 32% for large defects and 17% for small (< 10 cm²) defects.³⁷

Sublay prosthetic repair is sometimes referred to as the retromuscular approach. A sublay prosthetic repair is characterized by the placement of a large prosthesis in the space between the abdominal muscles and the posterior fascia, the transversalis fascia, or the peritoneum, depending on what part of the abdomen is being repaired (there is no posterior fascia inferior to the arcuate line).⁴³ The technique described

in this chapter is similar to that described by Flament, Vela-menta, Stoppa, and Wantz [see Figure 4].^{44,45} The operation was originally envisioned for treatment of large and multiply recurrent hernias in cases where most of the abdominal wall had to be reconstructed. Because it has proven so successful, it is now being increasingly used to repair smaller defects. Sublay prosthetic repair is currently considered the most effective conventional incisional hernia repair and is therefore the one against which all other procedures are measured.

Placing a mesh underneath the abdominal musculature can be achieved using multiple techniques. Intraperitoneal placement can be performed laparoscopically and is discussed in another chapter. Open approaches can also be used to place mesh intraperitoneally. This can be done using a dual-layer mesh. Unfortunately, this typically requires raising large subcutaneous flaps and substantial transfascial fixation sutures to prevent bowel from slipping around the sides of the mesh and subsequently risking obstruction. The mesh can also be placed in an extraperitoneal position either in the preperitoneal plane or the retrorectus space. This is our preferred method, which relies on the basic principles of the Stoppa approach for inguinal hernias and is described in detail here.

Step 1: Incision

The initial incision is typically midline and should remove all old scar tissue that might compromise subsequent wound healing. In certain patients with a large pannus, a transverse panniculectomy-type incision can be employed. Some authors advocate remaining in the extraperitoneal space throughout the dissection. This provides the distinct advantage of avoiding potential bowel complications; however, it can be a very tedious and difficult dissection plane, especially in large hernia sacs and complicated defects. It is our preference to enter the peritoneal cavity and perform a complete adhesiolysis to identify all defects and mobilize the entire abdominal wall.

Step 2: Entering the Retrorectus Plane

Several options exist for entering the correct plane in the lateral abdominal wall. One technique involves maintaining a preperitoneal dissection. This is similar to the groin dissection, but along the anterior abdominal wall, the peritoneum can be densely invested in the posterior rectus sheath, making this very difficult. Alternatively, the posterior rectus sheath can be entered at the linea alba. Graspers are placed on the linea alba and the posterior rectus sheath is incised just off the midline. This release is completed throughout the length of the incision and at least 5 cm beyond the defect in a cephalad-caudad orientation. The dissection is then carried laterally deep to the rectus muscle above the posterior rectus sheath. Below the arcuate line, this is above the transversalis fascia and peritoneum. The dissection is continued laterally to the linea semilunaris at the edge of the rectus muscle. In routine hernias, the rectus muscle is typically anywhere from 5 to 10 cm in width. This provides ample overlap of the mesh. However, in larger hernias and multiply recurrent hernias, often there is atrophy, or loss of the rectus muscle, and this dissection does not provide adequate mesh overlap. In these circumstances, several options exist. The lateral abdominal compartment can be accessed in either the intermuscular or preperitoneal plane. The intermuscular plane can be reached by incising the lateral border of the posterior rectus sheath. The plane between the transversus abdominis and the

internal oblique can be carried far laterally to obtain substantially more mesh overlap. One of the drawbacks of this approach is that the perforating nerves to the rectus muscle can be damaged, rendering it nonfunctional. In addition, the intercostal vessels travel within this intermuscular plane. Another approach involves entering the preperitoneal plane. This can be achieved by incising the posterior rectus sheath 1 cm medial to the linea semilunaris. Once this plane is entered (the preperitoneal plane or space), the dissection can be continued far lateral, all the way to the psoas muscle if necessary.

Step 3: Reapproximating the Posterior Rectus Sheath

The posterior rectus sheath, peritoneum, and transversalis fascia are reapproximated in the midline. Recreation of this anatomic plane completely excludes the viscera from the mesh. Alternatively, the hernia sac or a piece of absorbable mesh can be used to recreate this space.

Step 4: Mesh Placement

The mesh is placed in the retrorectus position. If necessary, the mesh can be secured to the Cooper ligament along the pelvis and placed under the xiphoid process. Several transfascial fixation sutures are placed through puncture sites in the lateral abdominal wall. These sutures are placed through the full thickness of the abdominal wall, with the knots placed below the skin. These sutures should be placed under moderate tension. By placing these sutures under tension, when they are tied, the rectus muscle is medialized and the forces are distributed to the lateral abdominal wall away from the midline. Securing the mesh to the lateral abdominal wall under tension also allows the rectus muscle to be reapproximated over the mesh without buckling of the prosthetic material.

In certain circumstances, the posterior rectus or preperitoneal plane cannot be created. In these situations, one can place the mesh intraperitoneally. However, a barrier mesh should be used to avoid bowel complications.

Step 5: Closure

After the mesh is secured, every attempt should be made to reapproximate the linea alba in the midline. This serves the functional purpose of restoring the native abdominal wall contour and function. Also, it covers the mesh to avoid potential wound complications and subsequent mesh sepsis.

There are single-center series with evidence of improved outcomes using this technique.⁴⁶ For example, in a Finnish study of 84 consecutive patients treated with a retromuscular polypropylene mesh repair and followed for 3 years, the recurrence rate was 5%. In a separate US study, no recurrences were reported in 102 patients after 28 months of follow-up.⁴⁷ A 2006 study from Sweden confirmed the superiority of this operation, reporting a 7.3% recurrence rate for sublay prosthetic repair, compared with 19.3% for onlay mesh repair and 29.1% for suture repair.⁴⁸ Sublay prosthetic repair has been successfully employed to treat massive hernias with substantial loss of domain.⁴⁹ A retrospective review from the Mayo Clinic evaluated their experience with a modified Rives-Stoppa technique using prosthetic mesh in complex incisional hernia repair over a 13-year period.⁵⁰ With a median follow-up of 59 months and 254 patients, their overall hernia recurrence rate was 5%, with most hernias being detected within 12 months of repair.

Figure 4 Incisional hernia repair. Illustrated is a retromuscular approach. (a) The anterior rectus sheath has already been incised, rotated medially, and closed in the midline. The space beneath the rectus abdominis is being developed. Dissection should continue to the lateral edge of the posterior rectus sheath, but care should be taken to prevent injury to the neurovascular bundles; denervation or abdominal wall necrosis is possible if these bundles are injured. (b) The prosthesis is prepared with U-shaped sutures. (c) A suture passer is used to push the two tails of each U stitch through separate musculofascial sites. However, the two tails exit through the same skin incision; this eventually allows the prosthesis to be firmly secured deep in the pocket. The sutures are tied above the skin, and the knot is secured down to the fascial level. The suture is cut under tension so that the tails will retract back into the skin incision, which is then closed. If the flaps permit, the sutures can be tied in the subcutaneous tissue and not passed through the skin. The disadvantage of this latter approach is that there are likely to be more problems with seromas because of the more extensive dissection. (d) A penetrating towel clip is used to release the skin dimples created by the gathering of subcutaneous tissue when the full-thickness sutures are tied. This measure prevents a potentially permanent deformity. It is important to inspect the sutures to confirm that they have not been disrupted. EAO = external abdominal oblique; IAO = internal abdominal oblique; TA = transversus abdominus.

Component Separation Repair

The concept of separating the lateral abdominal wall musculature, allowing medialization of the rectus muscle complex, was first described by Ramirez and colleagues in 1990.⁵¹ Based on cadaveric studies, up to 10 cm of unilateral advancement of the abdominal wall can be achieved with release of the external oblique aponeurosis. A distinct advantage of this approach is the ability to achieve midline closure and recreation of the linea alba. Unlike mesh repair in a bridging fashion, a dynamic abdominal wall can be achieved. A hindrance to broader acceptance of this technique is that the large lipocutaneous flaps created to access the lateral abdominal wall are associated with major wound morbidity.

Historically, component separation has been reserved for complicated hernias when synthetic mesh is contraindicated.^{52–54} A recent trial on large midline abdominal wall hernias randomized 39 patients to either component separation or prosthetic repair using antibiotic-impregnated ePTFE.⁵⁵ Hernia recurrence was not different between the component separation technique and prosthetic repair (56% versus 58%, respectively; p value > .05) following a 36-month follow-up period.⁵⁵ Wound-related complications, including infection and skin necrosis, were also not different between the component separation technique and prosthetic repair (53% versus 72% respectively; p value > .05). However, 54% of infections in the ePTFE group required reoperation for removal of infected mesh. On interim analysis, this latter event caused early cessation of the study. Given the morbidity associated with reoperation in the prosthetic repair group compared with the asymptomatic small hernia recurrences observed in the component separation technique group, the authors concluded that the component separation technique was a favorable repair option for giant midline hernias. Typically, after a component separation, there is still tension on the midline closure. For this reason, most authors advocate reinforcement with a prosthetic. Whether the addition of a prosthetic material (either biologic or synthetic) to reinforce the repair after component separation might reduce recurrence rates further has not been adequately evaluated in the literature.

Patients undergoing abdominal wall reconstruction for massive defects each require individualized preparation and consideration prior to surgery. Physiologic changes occur in both the abdominal and the thoracic cavities following definitive closure of these large defects. In addition to the general preoperative screening, each patient should be assessed for pulmonary status and the potential for return to routine daily activities. Additionally, smoking status is critical as patients who smoke are at significantly higher risk for wound complications. Since its original description in 1990, component separation has undergone several adaptations. We describe the traditional open approach and two newer techniques to achieving a more minimally invasive separation of components.

OPEN COMPONENT SEPARATION

Step 1: Incision

A long midline incision or transverse panniculectomy-type incision is made through the scar to expose the hernia. The hernia sac is dissected up to its neck, deep to the fascial edge.

Step 2: Creation of Flaps

The lipocutaneous flap is dissected away from the anterior sheath of the rectus abdominis and the aponeurosis of the external abdominal oblique muscle. A technique that may help decrease skin flap necrosis is to preserve the periumbilical perforators.⁸ There are no exact landmarks to delineate the lateralmost extent of this flap. The surgeon must bimanually assess the rectus muscle belly. Once the lateral edge of the rectus is palpated, the dissection is carried 2 cm lateral to the linea semilunaris.

Step 3: Incising the External Oblique Muscle

The aponeurosis of the external oblique muscle is transected longitudinally about 2 cm lateral to the rectus sheath, with care to avoid cutting into the linea semilunaris [see Figure 5]. Transecting the linea semilunaris will result in a

Figure 5 Component separation repair. Depicted is the technique of component separation, as described by Ramirez and colleagues.⁵¹ (a) A longitudinal incision is made in the aponeurosis of the external oblique muscle (1) approximately 2 cm lateral to the rectus sheath, overlapping the hernia defect caudally and extending 5 to 7 cm cranial to the costal margin. Additional length can be gained by incising the posterior rectal sheath (2). (b) The external oblique muscle is separated from the internal oblique muscle as far laterally as possible. Care must be taken not to damage the neurovascular structures that run between the internal oblique muscle and the transversus abdominis to enter the rectus sheath on its posterolateral side (black line). A¹, A² = cut edges of the external oblique aponeurosis; B¹, B² = cut edges of the posterior rectus sheath.

full-thickness defect and a subsequent lateral hernia. If the surgeon inadvertently begins incising the external oblique muscle too medially, he or she runs the risk of potentially transecting the internal oblique fascia too. Transecting the internal oblique muscle will likely result in a lateral abdominal wall bulge. By making the incision lateral on the external oblique muscle, the internal oblique muscle is often muscular and can be clearly delineated from the external oblique. This incision is extended cranially onto the muscular components of the external abdominal oblique to about 5 to 7 cm above the costal margin and caudally to the inguinal ligament. The external oblique muscle is then separated from the internal oblique muscle in the avascular plane to the posterior axillary line.

Step 4: Posterior Rectus Sheath Release

If primary closure is still not possible without undue tension, 2 to 4 cm of additional length can be gained by separating the posterior rectus sheath from the rectus abdominis.

Step 5: Mesh Placement

Depending on the nature of the case (i.e., clean or contaminated), synthetic or biologic mesh, either in the retrorectus or intraperitoneal position, with a minimum 3 to 4 cm of tissue-mesh overlap can be placed. Others have described onlay positioning of the mesh after open component separation.^{39,56} Technically, onlay mesh positioning is easier than underlay placement. However, the mesh is then placed in the subcutaneous position, with a fairly high potential for wound breakdown and mesh exposure. Additionally, the mesh is placed below a devascularized subcutaneous fatty tissue, potentially impeding ingrowth.

Step 6: Skin Closure

Excess skin should be liberally resected. Resecting excess skin provides two distinct advantages: the most devascularized tissue is removed and excess dead space is reduced. Finally, the subcutaneous space should be widely drained with the use of Jackson-Pratt drains.

ENDOSCOPIC COMPONENT SEPARATION

In an effort to avoid the significant tissue trauma and the large open surface areas created following the open component separation technique, endoscopic approaches have been described.^{57–60} This minimizes the lipocutaneous flaps created in the open approach and can be used in conjunction with a planned laparotomy. Adaptations from its original approach have been made over time. This technique maintains the same principles as the open approach, which is to achieve medialization of the abdominal wall through lateral release of the external abdominal oblique fascia.

Step 1: Incision

In the setting of contaminated single-stage abdominal wall reconstruction, a standard laparotomy incision is commenced and the major infectious issues are addressed, including takedown of fistulas or removing an infected prosthetic. The entire anterior abdominal wall is freed of adhesions,

and the defect size is assessed. Those cases that will not close primarily undergo component separation. There is no absolute indication for this as all patients have a different level of compliance to their abdominal wall. A more compliant abdominal wall will come together more easily at the midline than one that is not very compliant. Generally, good surgical judgment, coupled with realistic expectations, should guide the decision-making process.

Step 2: Initial Component Separation Incision

Once a component separation is deemed necessary, a 1 cm incision just inferior to the tip of the 11th rib is made and the external abdominal oblique is identified with blunt dissection and Kocher clamps. The avascular plane between the external abdominal oblique and the internal abdominal oblique is identified by use of retractors. Careful identification of the correct anatomic plane is imperative at this juncture to avoid placing the dissecting balloon in the wrong plane and requiring conversion to an open procedure.

Step 3: Balloon Dissector

A bilateral inguinal hernia balloon dissector is inserted in a caudal direction toward the pubic tubercle. Under direct visualization, the balloon is inflated and the orientation of the muscle fibers is confirmed.⁶⁰ A structural balloon port is placed, and insufflation pressures of 10 to 12 mm Hg are maintained. The camera tip bluntly completes the posterior lateral dissection.

Step 4: External Oblique Release

A 5 mm port is placed in the posterior axillary line. This port needs to be quite lateral to obtain the appropriate angle to incise the external oblique fascia. Much like in the open approach, the linea semilunaris should be carefully identified and avoided to prevent a lateral hernia. Anatomically, the linea semilunaris is identified at the junction of the external and internal oblique. Typically, scissors and cautery are used to release the external oblique fascia to the inguinal ligament.

Step 5: Cephalad Dissection

Another 5 mm port is placed medially through this inferior release to be used for the cephalad release of the external abdominal oblique fascia and muscle. The camera is now positioned in the lateral trocar. Given that the external oblique is typically quite muscular at its cephalad extent, some form of ultrasonic dissection is helpful in maintaining hemostasis. The external oblique is then released for at least 5 to 7 cm above the costal margin. Once this is performed bilaterally, it completes the endoscopic component separation and the surgery.

Reinforcement or bridging of a midline defect for both the open and endoscopic approaches can be performed with mesh in the retrorectus or intra-abdominal position with lateral transfascial fixation sutures. The exact technique regarding mesh placement is still under debate. Biologic mesh may be used in the setting of contamination. Synthetic mesh can be used for elective clean cases. If synthetic mesh needs to be placed in the intraperitoneal position, a synthetic mesh of choice with an antiadhesive side should face the bowel.

COMPLICATIONS

There is overwhelming proof that tension-free prosthetic repairs yield lower recurrence rates than direct suture repairs. In a Medline search for complications of incisional hernia repair, recurrence rates ranged from 31 to 63% for direct suture repairs and from 0 to 32% (mostly less than 10%) for prosthetic repairs.^{61,62} Although the primary adverse outcome of hernia repair is recurrence, the short-term morbidity of open hernia repair must also be assessed. In one meta-analysis, the overall complication rate after open repair was 27%.⁶³ Ileus, postoperative pain, sepsis, fistulization, and necrotizing fasciitis have all been documented. Tissue response, which is variable from person to person, can be so intense that the prosthetic material is deformed by contraction. Erosion can result in intestinal obstruction or fistulization, especially if there is physical contact between the intestine and the prosthesis.^{64,65}

Prosthesis-related infection, although it occurs less with the laparoscopic technique, remains a major problem with open incisional hernia repairs. A pooled analysis of randomized trials comparing primary versus mesh repair of incisional hernias found an overall 10% infection rate.³⁸ Prosthesis-related infection occurs in as many as 25% of repairs in some series, delays healing for prolonged periods, and is one of the most important risk factors for recurrence. Higher rates of prosthesis infection are associated with preexisting infection, ulceration of the skin overlying the hernia, obesity, incarcerated or obstructed bowel within the hernia, and perforation of the bowel during hernia repair. Seromas are common, especially when a large prosthesis is required or there has been extensive flap dissection of the subcutaneous layer from the fascia. Untreated seromas can become infected secondarily. Suction drains can be useful, but there is little guidance in the literature as to appropriate times for removal. Drains can both remove bacteria or function as a two-way street, allowing seeding of the mesh. Strategies for preventing and managing seromas are largely based on empirical evidence and personal opinion; objective data are virtually nonexistent. It is not always necessary to remove the mesh if infection develops. A trial of local wound care after opening the incision and debriding the infected area is warranted. Some authorities believe that ePTFE prostheses are less prone to infection; however, once infection is established, ePTFE prostheses, unlike mesh prostheses, are almost never salvageable.

Laparoscopic Ventral Hernia Repair

Le Blanc and Booth were the first to describe successful laparoscopic ventral hernia repair in 1993.⁶⁶ Several technical benefits are ascribed to a laparoscopic approach, including the opportunity to evaluate the entire abdominal wall for other smaller, Swiss cheese–like defects that may otherwise be missed and allowing for wide underlay mesh placement while avoiding large tissue dissection and the associated wound morbidity. Studies with varied design methodologies have compared a laparoscopic approach with an open approach on several important outcome parameters, including wound morbidity, mesh infections, hernia recurrence, and hospital length of stay.

One of the largest series evaluating the safety and efficacy of laparoscopic ventral hernia repair was reported in 2003.⁶⁷ In this 10-year study, the authors reported a 3.6% conversion

rate from laparoscopic repair to open repair, an average length of stay of 2.3 days (0 to 33 days), and an overall complication rate of 13%, with an overall infection rate of 1.8% (including wounds and mesh infection). Other important complications reported included bowel or bladder injury (1.7%), prolonged ileus (3%), prolonged seroma (2.6%), and prolonged pain (1.6%). Following an average 20-month follow-up (range 0 to 96 months), they reported a 4.7% hernia recurrence rate. Important factors associated with their recurrences included larger hernias, increased operative times, history of prior hernia repairs, and postoperative complications. A more recent prospective randomized study of open versus laparoscopic incisional hernia repair supported this study with similar findings, including improved rates of complications, decreased hospital length of stay, and quicker return to work in the laparoscopic group.⁶⁸ Given similar patient characteristics and an average defect size of approximately 9 to 10 cm, the authors noted a decrease in postoperative complications (16% versus 29%), including decreased wound complications (1.1% versus 8.2%), for the laparoscopic group. Hospital length of stay (2.7 versus 9.9 days), rates of complications (16 versus 29%), and quicker return to work (13 versus 25 days) were significantly decreased in the laparoscopic group. Hernia recurrences were similar at approximately 2% after an average 24-month (range 16 to 15 months) follow-up in each group.

Other studies have also described benefits similar to those of a laparoscopic approach for ventral hernia repair but point toward a need to standardize issues related to patient selection. A recent meta-analysis summarized the results of five randomized controlled trials comparing open versus laparoscopic ventral hernia repair.⁶⁹ This study supported the associated decreased length of stay and decreased rates of complications reported by other studies. However, the authors were unable to find decreases in operative time, pain, and recurrence between the two groups. An important contributor to this lack of difference was attributed to the heterogeneity that existed across the various study methodologies. This resulted from the lack of double-blinded randomized trials, patient selection factors such as the varied hernia sizes included across studies, and the varied open techniques being compared. This subsequently underscores the need to clarify these important variables within the context of a well-defined multicenter trial. Furthermore, there are still areas of significant controversy that require further well-controlled trials, such as the method of securing the mesh in place (sutures, tacks, fibrin glue, or a combination), the best approach to address postoperative pain related to mesh fixation techniques, and the management of seromas.

A laparoscopic approach might have distinct advantages over an open ventral hernia repair for obese patients. As obesity has been identified as a risk factor for wound infections and recurrence in open surgery, studies have investigated the safety and efficacy of laparoscopy for this group of patients.^{70,71} Although comparable decreased rates of complications such as wound and mesh infections are reported in obese patients, it is unclear if the same benefit of decreased recurrence rates applies this population. A multi-institutional case series of 901 laparoscopic ventral hernia repairs compared outcomes for patients with a body mass index (BMI) above 40 versus

those with a BMI less than 40.⁷¹ Although similar improved rates of conversion to open repair ($\approx 2.5\%$) and mesh infections ($\approx 1\%$) were found between the two groups, the rates of recurrence were higher in the obese group (BMI ≥ 40 ; 8.3 versus 2.9%) and had an associated fourfold risk after a 19-month follow-up. Although this rate of 8% at 19 months might be acceptable relative to an open approach, it is important that obese patients understand that their rates of recurrence following laparoscopic repair may differ from those of their less obese counterparts. Several issues further complicate the decision to perform surgery in this select group of patients, such as the timing of gastric bypass surgery in relation to ventral hernia repair and the indications for panniculectomy. Although some small studies have attempted to evaluate this question, there are no high-quality studies available to guide answers to these complex problems.

As the benefits of an open versus a laparoscopic approach for varied groups of patients become more defined, an important criterion for choosing an approach is surgeon comfort. A laparoscopic ventral hernia repair, particularly for more complex patients with multiple prior surgeries, requires a special skill set. Here we describe our technique for laparoscopic ventral hernia repair.

Step 1: Intraoperative Patient Preparation

Following general anesthesia, the patient should be placed in the supine position, arms abducted, with appropriate padding. Gastric and bladder decompression should be performed with the aid of a nasogastric tube and Foley catheter prior to entering the abdominal cavity. A three-way Foley catheter is used for hernias below the umbilicus to aid in identifying and potentially mobilizing the bladder for mesh placement. Appropriate antibiotic and venous antithrombosis prophylaxis should be administered.

Step 2: Gaining Access to the Abdominal Cavity

The initial access port (10 or 12 mm) can be placed in the right or left upper quadrant using an open cut-down technique. A 5 mm 30° laparoscope is preferred to have adequate visualization of the anterior abdominal wall and allow placement through any trocar. Two to three other ports (5 mm) can be placed along the same side of the lateral abdominal wall under direct laparoscopic visualization. As a general rule, these ports should be placed as far laterally as possible to the midline defect to allow sufficient distance to place a large piece of mesh and to allow the surgeon to work in the midline without difficulty.

Step 3: Adhesiolysis and Defect Measurement

To avoid bowel injury, we prefer use of sharp dissection. If bleeding is encountered, liberal use of clips may be applied. If any part of this step becomes too challenging and the repair is compromised, conversion to an open repair should be considered. When working near the bladder, if there is any concern for an inadvertent bladder injury, the three-way Foley catheter can be used to fill the bladder and inspect for any evidence of leak. Following completion of adhesiolysis, the defect can be measured in preparation for mesh placement. Under direct laparoscopic visualization, long spinal needles are placed intra-abdominally along the edge of the

hernia defect. A 15 cm ruler is then placed intra-abdominally and used to measure the hernia defect under standard insufflation pressures and estimate the mesh size required for repair.

Step 4: Mesh Placement

Following defect measurement, the desired mesh can be cut with the goal of achieving an additional 4 to 5 cm of mesh overlap. Given its intra-abdominal position, either a dual-sided antiadhesive mesh or PTFE mesh should be used for this repair. The cephalad and caudal ends of the mesh can be marked to guide intra-abdominal orientation and placement. Nonabsorbable monofilament or PTFE sutures are secured in four quadrants of the mesh, with the knot landing on the ingrowth-promoting side. The mesh can then be rolled and inserted through the 10 mm trocar. Transfascial fixation sutures are additionally placed with suture passers at approximately 5 cm intervals to further secure the mesh in place. All knots are buried in the subcutaneous space. Additionally, helical tacks are placed circumferentially every 5 mm to secure the mesh in place at the edges.

Step 5: Postoperative Management

Most laparoscopic ventral hernia repairs require overnight admission secondary to perioperative pain management. Despite the minimally invasive nature of the procedure, most patients experience significant discomfort and the average length of hospital admission ranges from 2 to 4 days. We place an abdominal binder on all patients for 6 weeks to reduce seroma formation. Patients are restricted from heavy lifting for at least 6 weeks.

COMPLICATIONS

Special consideration should be given to complications associated with laparoscopic ventral hernia repair. An enterotomy is a critical complication of a laparoscopic approach that may occur while achieving abdominal cavity access or during adhesiolysis. It has been reported to occur in 1 to 6% of cases, with greater challenges encountered in the reoperative abdomen.^{67,72–74} Varied methods of accessing the abdominal cavity have been described, with no prospective randomized trial evaluating the true risk associated with the several available approaches. Although there is no standard way to access the abdominal cavity prior to pneumoperitoneum, an open cut-down technique with access under direct visualization may provide a safer route for complex patients. Extensive adhesiolysis, particularly in the patient with multiple prior surgeries and with prior intra-abdominal mesh placement, is another high-risk opportunity to inadvertently cause an enterotomy. Judicious use of cautery and opting for sharp dissection with the use of clips for hemostasis may help decrease cautery-related injury. In situations where there are dense adhesions onto intra-abdominally placed mesh, resecting the involved piece of mesh and bowel off the abdominal wall allows for safer clearance of the abdominal wall in preparation for mesh placement. Whether an enterotomy is encountered or questioned, conversion to an open approach is a safe next step to the management of this complication as diagnosing a delayed enterotomy is associated with increased morbidity and mortality.⁷⁵ The ideal surgical management to an enterotomy is controversial and in some cases may require delaying definitive hernia repair.

Special Circumstances

LOSS OF ABDOMINAL DOMAIN

Loss of abdominal domain is a poorly understood phenomenon that lacks clear definitions in the literature. In its simplest terms, it implies a massive hernia where the herniated contents have resided for so long outside the abdominal cavity that they cannot simply be replaced into the peritoneum. Unfortunately, several circumstances can result in this occurrence, and each poses unique reconstructive challenges. We typically divide loss of domain hernias into those in which there is contamination or no contamination. Next, each group is subcategorized into those patients with a small hernia defect and a large mushroom cloud of hernia contents and those patients with a massive abdominal wall defect and a massive hernia sac. In the former group, the challenges are mainly focused around having the patient accommodate the abdominal contents. In the latter group, not only must the patients be able to accommodate the abdominal contents, but the surgeon must also use various reconstructive methods to rebuild the abdominal wall.

In approaching these patients, the surgeon must give ample preoperative evaluation and clearance. In particular, the patients should be counseled as to the potential morbidity and mortality of these reconstructive efforts. The surgeon and the patient must set reasonable goals as to what can be accomplished. First, the abdominal contents must be returned to the abdominal cavity without causing respiratory embarrassment and hemodynamic compromise. In these circumstances, the use of progressive preoperative pneumoperitoneum and staged mesh excision has been described.^{76,77} After the contents are returned to the abdominal cavity, the reconstructive procedure must begin. Depending on the circumstances, a retrorectus repair, a bridged repair, component separation, and serial mesh excision may all be appropriate.⁷⁸ These procedures are technically demanding, require ample hospital resources, and likely should be attempted only in high-volume centers.

VENTRAL HERNIA REPAIR IN THE SETTING OF CONTAMINATION

A dilemma arises when a patient has a large incisional hernia and the wound is contaminated either by skin infection or by injury to the bowel during the repair at the time of adhesiolysis. In this situation, a nonabsorbable mesh would have a significant chance of becoming infected, and an enterocutaneous fistula could complicate matters further. In the past, the use of absorbable mesh made of polyglycolic acid was recommended to prevent evisceration.^{79,80} This staged approach to repair a contaminated ventral hernia would result in granulation tissue development over the mesh, allowing for subsequent skin grafting. The mesh itself is absorbed in about 3 weeks, leaving no permanent foreign body to serve as a persistent focus of infection. Unfortunately, recurrence of the incisional hernia is nearly inevitable and leads to a multistage approach to a contaminated abdominal wall defect. Single-stage repairs for this complex problem have been reported in the literature, particularly in conjunction with component separation technique.^{59,81} Currently, many surgeons prefer to use one of the newer biologic prostheses in this setting to achieve closure or add repair reinforcement. This has now

become the best indication for these very expensive materials. Long-term data are not yet available.

Periumbilical Hernia Repair

GASTROSCHISIS

This life-threatening condition is seen in the newborn. It may also be found in the fetus during ultrasound examination of a pregnant patient. There is full-thickness deficiency of the abdominal wall, to the right of a normal umbilicus, through which the bowels protrude. There is no hernial sac.

OMPHALOCELE (EXOMPHALOS)

Like gastroschisis, this condition is seen in the fetus in utero and in the newborn. It is a hernia into the umbilical cord; the hernia contents are therefore covered by Wharton jelly and amnion.

UMBILICAL AND PARAUMBILICAL HERNIA

Unlike an omphalocele, an umbilical hernia is covered by skin. If the defect is located to one side of the umbilicus, it is called a paraumbilical hernia (this variant is more common in adults). Umbilical hernias developing during childhood are congenital, whereas those developing during adult life are acquired. Accordingly, in adult patients, it is important to look for an underlying cause of increased intra-abdominal pressure (e.g., ascites or an intra-abdominal tumor). The differential diagnosis of an umbilical hernia includes caput medusae of varices at the umbilicus from portal hypertension, a metastatic tumor deposit (the so-called Sister Mary Joseph node), a granuloma, an omphalomesenteric duct cyst, and a urachal cyst.

Management of umbilical hernia is determined by the age of the patient. The majority of hernias occurring in children younger than 2 years will heal spontaneously; therefore, watchful waiting is the rule, and only symptomatic hernias are operated on. In children older than 2 years and in adults, surgical correction is required, with the type of repair employed depending on the size of the hernia. If the defect is small (< 3 cm), a direct suture repair may be performed. For larger umbilical and paraumbilical hernias, particularly those in adults, a mesh repair is preferred. The sac is dissected away from the undersurface of the rectus and the linea alba circumferentially and then reduced into the abdomen. If the peritoneum remains intact, a mesh prosthesis may be placed in a subfascial position and secured with sutures. If the abdomen is entered, a dual-layer prosthesis with an adhesion barrier on the visceral side is recommended. In a series of 100 adult patients with a median follow-up period of 4.5 years, the recurrence rate was 11.5% for suture repairs and 0% for mesh repairs.⁸²

A patient with an umbilical hernia and cirrhosis with or without ascites presents a challenging scenario to the general surgeon. Over their lifetime, a patient with cirrhosis has a 20% risk of developing an umbilical hernia, and in the presence of ascites, the risk is as high as 40%.^{83,84} Knowing the surgical complications that can occur following operating on a cirrhotic patient creates a tempting scenario for delayed umbilical hernia repair. However, with advancing disease and progression of umbilical hernia come greater risks, including

incarceration, skin ulceration, perforation, leakage of ascitis, bacterial peritonitis, and possibly evisceration. Although there are certainly risks with elective repair in a patient with cirrhosis, the counterpart morbidity and mortality associated with emergent repair are far greater and have prompted many surgeons to consider early repair.

Aggressive control of ascites is necessary before and after surgery to ensure an improved repair. Several studies have shown that when ascites is controlled, hernia repair outcomes are improved.⁸⁵ In addition to medical approaches to controlling ascites, other approaches, such as concomitant peritoneovenous shunting, transjugular intrahepatic portosystemic shunt, or the use of a peritoneal dialysis catheter, have been described but mainly through descriptive studies.⁸⁵ A recent review of 34 patients with a symptomatic umbilical hernia and cirrhosis showed greater morbidity and mortality in patients in the watchful nonoperative group compared with those who underwent elective repair with primary closure.⁸⁶ A comparison of cirrhotic and noncirrhotic patients undergoing repair of a noninguinal hernia had similar morbidity and mortality when repair was performed electively; however, higher morbidity and a nearly sevenfold mortality was observed in the cirrhotic patients when surgery was emergent.^{84,87} Given the challenges of conducting a randomized study on such a small subset of patients, questions that remain unanswered include primary repair versus mesh repair, type of mesh to be used, timing for elective repair, and use of adjunct interventional procedures for ascitic control.

Miscellaneous Ventral Abdominal Wall Hernia Repairs

EPIGASTRIC HERNIA

Epigastric hernias occur through a single defect or multiple defects in the linea alba. In most patients with these hernias, only a single decussation of the fibers of the linea alba is present, as opposed to the triple decussation seen in most persons.⁸⁸ The reported incidence of epigastric hernia ranges from less than 1% to as high as 5%. Hernias are two to three times more common in men than in women, and 20% are multiple. Most defects are smaller than 1 cm and contain only incarcerated preperitoneal fat, with no peritoneal sac. For this reason, they generally cannot be visualized laparoscopically.

The usual complaint is a painful nodule in the upper midline. As a rule, reduction of the preperitoneal fat followed by simple closure of the defect resolves the complaint. Given the relatively high recurrence rate (up to 10%), some surgeons prefer to place a postage stamp-sized piece of prosthetic material in the preperitoneal space to reinforce the repair. Others bridge the defect by suturing the prosthesis circumferentially. Some authorities recommend exposure of the entire linea alba because of the incidence of multicentricity. This practice leads to unnecessary morbidity. Instead, we make a small incision with the patient under local anesthesia and explain to him or her that additional repairs may be required later.

Left untreated, an epigastric hernia can become large enough to develop a peritoneal sac into which intra-abdominal contents can protrude. Usually, however, the sac is wide, and serious complications are infrequent.

DIASTASIS RECTI

In diastasis recti, the two rectus abdominis muscles are separated quite widely, and the linea alba is stretched and protrudes like a fin. Although the protrusion is easily reducible and almost never produces complications, many patients find it unsightly and request treatment. Most patients, when reassured that this is, in fact, not a true hernia, will decline further surgical intervention. The usual therapy involves removing a strip of the weakened linea alba and reapproximating it; however, this could result in tension, which in turn might lead to recurrence. The alternative would be a mesh repair.

PARASTOMAL HERNIA

Parastomal hernia is one of the most common complications of stoma formation. By definition, the creation of a stoma implies some form of an abdominal wall hernia. There is good evidence to suggest that more than 50% of patients will eventually be found to have a paracolostomy hernia if followed for longer than 5 years.⁸⁹ The rate of herniation with small bowel stomas is also discouraging, although less so than that with colostomies. The results of parastomal hernia repair are particularly dismal, with recurrence being the rule rather than the exception.

Some parastomal hernias can be accounted for by poor site selection or technical errors (e.g., making the fascial opening too large or placing a stoma in an incision), but the overall incidence is too high to be explained by these causes alone. Placement of the stoma lateral to the rectus sheath is widely touted as a cause of parastomal hernia, but high-quality scientific evidence to support this claim is not available. Obesity, malnutrition, advanced age, collagen abnormalities, postoperative sepsis, abdominal distention, constipation, obstructive uropathy, steroid use, and chronic lung disease are also contributing factors.^{90,91}

Newer techniques for stoma construction, such as extraperitoneal tunneling, have had little impact on the incidence of parastomal hernia. Fortunately, patients tolerate these hernias well, and life-threatening complications, such as bowel obstruction and strangulation, are rare. Most are asymptomatic. Routine repair, therefore, is not recommended; repair is appropriate only when there is an absolute or relative indication [see Table 7]. If repair is considered, patients must be informed that there is a significant chance that the hernia will recur.

Table 7 Indications for Repair of Parastomal Hernia

Absolute indications
Obstruction
Incarceration with strangulation
Relative indications
Incarceration
Prolapse
Stenosis
Intractable dermatitis
Difficulty with appliance management
Large size
Cosmesis
Pain

Three general types of parastomal hernia repairs are currently performed: (1) fascial repair, (2) stoma relocation, and (3) prosthetic repair. Fascial repair involves local exploration around the stoma site, with primary closure of the defect. This approach should be considered of historical interest only because the results are so poor. We reserve this approach for elderly patients or in emergent situations as a bridge to a future definitive repair. Stoma relocation yields much better results and is considered the procedure of choice by many surgeons. This approach is especially appropriate for patients who have other stoma problems, such as skin excoriation or suboptimal stoma construction. The use of a permanent prosthesis with a stoma relocation is not generally recommended because of the inherent danger of contamination. However, biologic mesh reinforcement has shown some promise in reducing recurrence rates. Stoma relocation is a significantly more invasive procedure and subjects patients to a triple threat of hernia recurrence: (1) at the old stoma site, (2) at the new stoma site, and (3) in the laparotomy incision used to move the stoma. Given these risks, we typically place a large sheet of biologic mesh in the retrorectus position. This mesh is keyholed around the new stoma site and is used to reinforce the old stoma site and the midline closure.

Prosthetic repair can provide a reasonable outcome, but it is necessary to accept the complications inherent in the placement of a foreign body. The stoma exit site must be isolated from the surgical field to lower the risk of prosthesis infection. The prosthesis can be placed extraperitoneally by making a hockey-stick incision around the stoma, with care taken to ensure that the incision is outside the periphery of the stoma appliance. Once the subcutaneous tissue is divided, dissection proceeds along the fascia until the sac is identified and removed. The defect is then closed with an overlying prosthesis buttress sutured in place. Alternatively, the fascial defect is bridged with the prosthesis for a tension-free repair.

The extraperitoneal approach seems logical but can be technically demanding in that it is sometimes difficult to define the entire extent of the hernia defect. Moreover, the considerable undermining involved can lead to seroma formation, eventual infection, or peristomal skin necrosis. As an alternative, an intra-abdominal prosthetic approach has been described that is theoretically attractive because it avoids the local complications of the extraperitoneal operation and incorporates the mechanical advantage gained by placing the prosthesis on the peritoneal side of the abdominal wall.^{92,93} Intra-abdominal pressure then serves to fuse the prosthetic material to the abdominal wall rather than being a factor in recurrence. Either ePTFE, polypropylene, or polyester mesh with an adhesion barrier can be used for the prosthesis. One technique is to slit the prosthesis and create a keyhole in its center and then suture this directly around the peritoneal side of the stoma so that it widely overlaps the hernia defect. Sugarbaker's practice is to mobilize the bowel thoroughly and then lateralize it with the prosthesis, in effect creating a long tunnel in addition to covering the hernia defect.⁹³ The detractors of the intra-abdominal approach argue that the risk of complications (e.g., adhesive bowel obstruction and fistula formation) outweighs the advantages. The intra-abdominal approach is particularly well suited for adaptation to laparoscopic methods.⁹⁴⁻⁹⁶

SPIGELIAN HERNIA

A spigelian hernia, first described 400 years ago by the Flemish anatomist Adriaan van den Spiegel, is a hernia through a defect in the spigelian fascia.⁹⁷ The spigelian fascia is the area between the semilunar line and the lateral border of the rectus abdominis. The majority of spigelian hernias occur just below the arcuate line, where the posterior rectus sheath becomes deficient. This region, known as the spigelian belt, is a band between the iliac crest and a line drawn 6 cm above [see Figure 6].⁹⁸ These rare hernias are being reported with increasing frequency: there are more than 100 cases in the surgical literature.

A spigelian hernia may present as a bulge lateral to the rectus. However, because many of these hernias are interparietal, they may not be clinically apparent; often they are picked up incidentally during laparoscopy. A significant percentage of patients present with an incarcerated or even strangulated hernia. If such a hernia is interparietal, the diagnosis frequently is not made until a laparotomy is done for treatment of the acute process.

The standard treatment is operative repair.⁹⁹ A transverse incision is made over the bulge. The anterior rectus sheath is incised transversely, and the sac is dissected as far as its neck and either excised or inverted. The defect is then repaired with a continuous suture of nonabsorbable material. Alternatively, a mesh may be placed in the defect and sutured to the edges of the defect. Laparoscopic methods are increasingly being employed to repair spigelian hernias.¹⁰⁰

RICHTER HERNIA

In a Richter hernia, part of the bowel wall herniates through the defect. The herniated bowel wall may become ischemic and gangrenous, but intestinal obstruction does not occur. The overlying skin may be discolored. The herniated bowel wall is exposed by opening the sac, and the neck of the sac is enlarged to allow delivery of the bowel into the wound. The gangrenous patch is excised, and the bowel wall is reconstituted. The hernia is then repaired.

SUPRAVESICAL HERNIA

Supravesical hernias develop anterior to the urinary bladder as a consequence of failure of the integrity of the transversus abdominis and the transversalis fascia, both of which insert into the Cooper ligament. The preperitoneal space is continuous with the retropubic space of Retzius, and the hernia sac protrudes into this area. The sac is directed laterally and emerges at the lateral border of the rectus abdominis in the inguinal region, the femoral region, or the obturator region. It may therefore mimic a hernia from any of these areas and sometimes is associated with a hernia from one of these regions. It is important to recognize this hernia during groin exploration for a suspected groin hernia and then to repair the defect appropriately.

A variant of this hernia, known as an internal supravesical hernia, may also arise. These hernias are classified according to whether they cross in front of, extend beside, or pass behind the bladder. Bowel symptoms predominate in patients with these defects, and urinary tract symptoms may develop in as many as 30%. Treatment is surgical and is accomplished

Figure 6 Depicted is the spigelian hernia belt, with a diagrammatic representation of the relevant components of the anterior abdominal wall, including (1) the transversus abdominis, (2) the dorsal lamella of the rectus sheath (the rectus abdominis itself having been cut away), (3) the semicircular line (of Douglas), and (4) the spigelian aponeurosis.

transperitoneally via a low midline incision. The sac can usually be reduced without difficulty, and the neck of the sac should be divided and closed.

LUMBAR HERNIA

The lumbar region is the area bounded inferiorly by the iliac crest, superiorly by the 12th rib, posteriorly by the erector spinae group of muscles, and anteriorly by the posterior border of the external oblique muscle as it extends from the 12th rib to the iliac crest. There are three varieties of lumbar hernia:

1. The superior lumbar hernia of Grynfeltt. In this variety, the defect is in a space between the latissimus dorsi, the serratus posterior inferior, and the posterior border of the internal oblique muscle.
2. The inferior lumbar hernia of Petit. Here the defect is in the space bounded by the latissimus dorsi posteriorly, the iliac crest inferiorly, and the posterior border of the external oblique muscle anteriorly.
3. Secondary lumbar hernia that develops as a result of trauma—mostly surgical (e.g., renal surgery)—or infection.¹⁰¹ In the past, it was encountered relatively frequently as a consequence of spinal tuberculosis with paraspinal

abscesses but is less common today. Surgical repair is discouraged because the natural history is more consistent with that of diastasis recti than that of a true hernia. Denervation appears to play a significant role in the pathogenesis. In other words, this “hernia” reflects a weakness in the abdominal wall more than it does a dangerous hernia defect. Therefore, appropriate repair is commonly followed by gradual eventration, which is perceived by the patient as a recurrence.

Lumbar hernias should be repaired if they are large or symptomatic. A prosthesis or a tissue flap of some kind is usually required for a successful repair. A rotation flap of fascia lata can be used for inferior lumbar hernias. Bony landmarks limit anterior open approaches. We typically perform a preperitoneal Stoppa-type repair. If necessary, the mesh can be fixed to the iliac bone with orthopedic bone fixation devices.¹⁰² Laparoscopic repair of lumbar hernias is now being performed with increasing frequency and is proving successful.¹⁰³

28 INGUINAL HERNIA REPAIR

Simon Bergman, MD, MSC, FRCSC, and Liane S. Feldman, MD, FACS, FRCSC

In the United States, approximately 1,000,000 abdominal wall herniorrhaphies are performed each year, of which almost 80% are for inguinal or femoral hernias.¹ Worldwide, some 20 million groin hernias are repaired each year.² The lifetime risk of having to undergo an inguinal hernia repair is 27% for men and 3% for women.³ In male patients, indirect inguinal hernias are the most common type (more often located on the right), occurring approximately twice as frequently as direct inguinal hernias; femoral hernias account for a much smaller percentage. In female patients, indirect inguinal hernias are also the most common type, but femoral hernias are seen more frequently than direct hernias, which are rare in this population. Femoral hernias account for fewer than 10% of all groin hernias; however, 40% present as emergencies (i.e., with incarceration or strangulation), and mortality is higher for emergency repair than for elective repair. A two-peak theory has been described, stating that a new diagnosis of an inguinal hernia is most likely in patients younger than 1 year and in patients older than 55 years, although hernias can be diagnosed across any given age group.⁴
